On Probabilistic Computation Tree Logic

Frank Ciesinski, Marcus Größer {ciesinski|groesser}@cs.uni-bonn.de
Rheinische Friedrich Wilhelms Universität zu Bonn, Institut für Informatik - Abt. I, Römerstraße 164, 53117 Bonn

Abstract. In this survey we motivate, define and explain model checking of probabilistic deterministic and nondeterministic systems using the probabilistic computation tree logics PCTL and PCTL*. Juxtapositions to non-deterministic computation tree logic are made, algorithms are presented.

Keywords: PCTL, PCTL*, Discrete Time Markov Chains, Markov Decision Processes, scheduler, fairness, Deterministic Probabilistic Systems, Nondeterministic Probabilistic Systems, quantitative model checking.

1 Introduction and Overview

Model Checking is a fully automatic verification method for both hard- and software systems that has seen a very promising development for now almost 25 years. Numerous efficient methods have been proposed very successfully to attack the discouraging general complexity of Model Checking (see e.g. [12]). Various temporal logics were proposed to emphasize certain different aspects of models to be checked. Among them are logics to cover the behaviour of probabilistic systems. Taking probabilities into account in addition to nondeterministic behaviour expands the possibilities of modeling certain aspects of the system under consideration. While nondeterministic systems are considered in connection to underspecification, interleaving of several processes and interaction with the specified system from the outside, the probabilities can be exploited to model a certain probability of error or other stochastic behaviour both occurring in various real world applications, e.g. certain randomized algorithms or communication protocols over faulty media.

The development of probabilistic Model Checking can roughly be divided into two periods. With qualitative Model Checking, which's development merely took place in the 1980s, it is possible to decide whether a system satisfies its specification with probability 1. Many aspects of qualitative probabilistic Model Checking were outworked, such as the termination of probabilistic programs [27], the omega-automaton-based approach for Model Checking probabilistic (as well as non-probabilistic) systems [50, 52, 13], the tableaux based method [41] and Model Checking of probabilistic real-time systems [2]. In the 1990s the idea of qualitative Model Checking was extended to quantitative Model Checking where it becomes possible not only to check whether the specification is satisfied with
probability 1 but to specify arbitrary probability values \( p \in [0, 1] \). Model Checking algorithms were developed for the deterministic case (Discrete Time Markov Chains, DTMCs) [25,3] as well as for the nondeterministic case (Markov Decision Processes, MDPs) [14,15,17,18,10,8], including fairness [4].

In this survey we summarize the main results presented in the papers mentioned above and use the logic PCTL (Probabilistic Computation Tree Logic), which is commonly used corresponding to Discrete Markov Chains and Markov Decision Processes as the basic temporal logic [26,10]. It extends the temporal logic RTCTL (Real Time CTL, [19]). While RTCTL, as an extension to the common known temporal logic CTL, additionally provides discrete time properties such as

\[
\text{A property holds within a certain amount of (discrete) time ,}
\]

PCTL allows to state properties such as

\[
\text{A property holds within a certain amount of (discrete) time with a probability of at least 99\% .}
\]

Thus, PCTL supplies a formalism which adds probabilities in a certain way. Intuitively RTCTL allows it to state "hard deadlines" while PCTL is capable of stating so called "soft deadlines".

After making some basic definitions concerning probabilistic processes, the syntax and semantics of PCTL and PCTL* are defined, similarities and differences between PCTL and CTL (resp. PCTL* and CTL*) are outlined. Then for both the deterministic and the nondeterministic case model checking procedures are described, fairness is taken into concern as well.

The reader is supposed to be familiar with temporal logics and basic notions of probability theory. See e.g. [22,21,38,12].

# 2 Validation of Deterministic Probabilistic Systems

PCTL - like it is presented in this chapter - was introduced by Hansson and Jonsson [25] and concentrates on probabilistic model checking in connection with probabilistic deterministic systems (PDS). In essence a PDS is a state labelled markov chain and PCTL allows to check properties of the kind “starting from a state \( s \), a certain PCTL path formula holds with a probability of at least \( p^\ast \) using a probabilistic operator. This probabilistic operator may be seen as a counterpart to the \( \forall \) and \( \exists \) operator in CTL (i.e. it can be applied to path-formulae only). Similar to CTL as well, PCTL can be extended by relaxing the PCTL-syntax to PCTL*, which will be dealt with in section 2.5. We will firstly define essential structures for modeling probabilistic processes and the syntax and semantics of PCTL. As descriptions go along, certain similarities and differences to CTL are emphasized. Finally a model checking algorithm for PCTL is outlined.
2.1 Deterministic Probabilistic Systems

We define Probabilistic Deterministic Systems (PDS) which essentially are state labelled \textit{Finite Markov Chains} (we restrict ourselves to finite systems).

**Definition 1.** [Probability distribution]

Given a finite set \( S \), a probability distribution on \( S \) is a function

\[
\mu : S \rightarrow [0, 1] \quad \text{such that} \quad \sum_{s \in S} \mu(s) = 1.
\]

Given a probability distribution on \( S \), \( \text{supp}(\mu) \) denotes the support, i.e. the states \( s \) of \( S \) with \( \mu(s) > 0 \). For \( s \in S \), \( \mu^*_s \) denotes the unique distribution on \( S \) that satisfies \( \mu^*_s(s) = 1 \). With \( \text{Distr}(S) \) we denote the set of all probability distributions on \( S \).

**Definition 2.** [Finite markov chain]

A finite markov chain is a tuple

\[
M = (S, T, p),
\]

where

- \( S \) is a finite set,
- \( T \subseteq S \times S \) is a set of transitions and
- \( p : S \times S \rightarrow [0, 1] \) is a function such that for all \( s \in S \)
  - \( p(s, \cdot) \) is a probability distribution on \( S \)
  - \( (s, t) \in T \) iff \( t \in \text{supp}(p(s, \cdot)) \).

Throughout this article we will use the notation \( p_{uv} \) instead of \( p(u, v) \).

We also refer to \((S, T)\) as the underlying graph of \( M \). Note that \( T \) is total, so \((S, T)\) has no terminal nodes.

Normally a Markov Chain is equipped with a starting probability distribution. A Markov chain with a starting distribution induces a stochastic process on the set \( S \) of its states in a natural way. The probability to start in a certain state with step 0 is determined by the starting distribution. Moreover, being in state \( u \) in the \((n-1)\)th step, the probability of reaching state \( v \) with the \( n \)th step is equal to \( p_{uv} \). The fact, that those probabilities do not depend on the previous steps (\textit{history-independent} or \textit{memoryless}) is called the \textit{Markov Property}.

**Definition 3.** [Ergodic set]

Let \( G = (V, E) \) be a directed graph. We call \( C \subseteq V \) an \textit{ergodic set} of \( G \), iff \( C \) is a terminal strongly connected component of \( G \), i.e.

- \( \forall (u, v) \in E : u \in C \Rightarrow v \in C \)
- \( \forall u, v \in C : \exists \text{ a finite path from } u \text{ to } v \text{ in } G \)

An ergodic set is therefore a strongly connected component that cannot be left once the execution sequence reached one of its states. Given a markov chain \( M = (S, T, p) \), we call \( C \subseteq S \) an ergodic set of \( M \), if \( C \) is an ergodic set of the underlying graph of \( M \).
**Definition 4. [Probabilistic deterministic system (PDS)]**

A probabilistic deterministic system (PDS) is a tuple

\[ T_{PDS} = (M, AP, L, \bar{s}), \]

where

- \( M = (S, T, p) \) is a finite markov chain,
- \( AP \) is a finite set of atomic propositions,
- \( L \) is a labelling function \( L : S \to 2^{AP} \) that labels any state \( s \in S \) with those atomic propositions that are supposed to hold in \( s \) and
- \( \bar{s} \in S \) is the starting state.

![Diagram](image)

**Fig. 1.** PDS example: A very simple communication protocol.

In the sequel we just write \( T \) instead of \( T_{PDS} \). We now define the essential executional issues of a Probabilistic Deterministic System. Given a PDS \( T = (M, AP, L, \bar{s}) \) with \( M = (S, T, p) \) we define the following:

**Definition 5. [Path]**

A path of \( T \) is a finite or infinite sequence \( \pi = s_0, s_1, \ldots \) of states, such that \((s_i, s_{i+1}) \in T\) for all \( i \) under consideration.

Given a finite path \( \omega = s_0, s_1, \ldots, s_n \), we denote \( s_0 \) by first(\( \omega \)) and \( s_n \) by last(\( \omega \)). The length |\( \omega \)| of \( \omega \) is equal to \( n \). For an infinite path \( \pi \), the length is equal to \( \infty \). Given a path \( \pi = s_0, s_1, \ldots, s_i \) (finite or infinite) and \( i \leq |\pi| \), we denote the \( i \)-th state of \( \pi \) by \( \pi^i \) (i.e. \( \pi^1 = s_1 \)) and the \( i \)-th prefix by \( \pi^{\leq i} = s_0, s_1, \ldots, s_i \).

Given an infinite path \( \pi = s_0, s_1, \ldots \), we denote the suffix starting at \( \pi^i \) by \( \pi^{\geq i} \), i.e. \( \pi^{i+1} = s_{i+1}, \ldots \).

Furthermore we denote by \( \text{Paths}_{fin} \) (resp. \( \text{Paths}_{inf} \)) the set of finite (resp. infinite) paths of a given PDS and by \( \text{Paths}_{fin}(s) \) (resp. \( \text{Paths}_{inf}(s) \)) the set of finite (resp. infinite) paths of a given PDS starting at the state \( s \).

**Definition 6. [Trace]**

We define the trace of a (finite) path \( \pi = s_0, s_1, \ldots \) to be the (finite) word over
the alphabet $2^{AP}$ which we get from the following:

$$\text{trace}(\pi) = L(\pi^0), L(\pi^1), \ldots = L(s_0), L(s_1), \ldots$$

**Definition 7. [Basic cylinder]**
For $\omega \in \text{Paths}_{\text{fin}}$ the basic cylinder of $\omega$ is defined as

$$\Delta(\omega) = \{ \pi \in \text{Paths}_{\text{inf}} \;|\; \pi^{|\omega|} = \omega \}.$$

Let $s \in S$. Following markov chain theory and measure theory [33] we now define a probability space on the set of paths starting in $s$.

**Definition 8. [Probability space of a markov chain]**
Given a finite markov chain $M = (S, T, p)$ and $s \in S$, we define a probability space

$$\Psi^s = (\Delta(s), \Delta^s, \text{prob}_s),$$

such that

- $\Delta^s$ is the $\sigma$-algebra generated by the empty set and the basic cylinders over $S$ that are contained in $\Delta(s)$.
- $\text{prob}_s$ is the uniquely induced probability measure which satisfies the following:
  $$\text{prob}_s(\Delta(s)) = 1$$
  and for all basic cylinders $\Delta(s, s_1, \ldots, s_n)$ over $S$:
  $$\text{prob}_s(\Delta(s, s_1, \ldots, s_n)) = p_{ss_1} \cdots p_{ss_{n-1}s_n}$$

We now state a fact about ergodic sets that we will need later.

**Lemma 1. [Reaching an Ergodic set]**
Given a markov chain $M = (S, T, p)$, the following holds for all $s \in S$:

$$\text{prob}_s(\{ \pi \in \text{Paths}_{\text{inf}}(s) \;|\; \exists C \text{ ergodic set of } M \text{ s.t. } \forall c \in C : \pi^i = c$$

for infinitely many $i$'s}) = 1.

**Proof.** see [33]

This means that given a markov chain $M = (S, T, p)$ and an arbitrary starting state $s$ it holds that the stochastic process described by $M$ and $s$ will reach an ergodic set $C$ of $M$ and visit each state of $C$ infinitely often with probability 1. This concludes the preliminary definitions needed for PCTL-model checking.

We now define the syntax of PCTL.

### 2.2 The Syntax of PCTL

We define the PCTL syntax along with some intuitive explanations about the corresponding semantics when meaningful. The precise semantics of PCTL will be defined in a formal way in section 2.3 afterwards.
**Definition 9. [PCTL-syntax]**

The syntax of PCTL is defined by the following grammar:

1. **PCTL-state formulae**
   
   \[ \Phi ::= \text{true} \mid a \mid \Phi_1 \land \Phi_2 \mid \neg \Phi \mid [\phi]_{\leq p} \]

2. **PCTL-path formulae**
   
   \[ \phi ::= \Phi_1 U^{\leq t} \Phi_2 \mid \Phi_1 U \Phi_2 \mid X \Phi \]

where \( t \in \mathbb{N}, p \in [0, 1] \subseteq \mathbb{R} \), and \( a \in AP, \preceq \in \{>, \geq, \leq, <\} \)

The set of all PCTL-formulae is \( \text{form}_{PCTL} = \{ f : f \text{ is a PCTL formula} \} \) where we assume a fixed set of atomic propositions. The special symbol \( \preceq \) is used for "~, "~", "~"" or "~"" respectively.

Other Boolean operators (i.e. \( \lor, \neg, \leftrightarrow \)) are not defined explicitly but can be derived from \( \land \) and \( \neg \) as usual. State formulae represent properties which can be any atomic proposition (i.e. \( a \in AP \)) or Boolean combinations of them as well as \([ \ ]_{\preceq p}\) properties that require a certain amount (w.r.t. a measure, see definition 8) of paths to exist starting in the current state and satisfying the enclosed path formula. Path formulae involve the strong until (be it the bounded \( U^{\leq t} \) or the unbounded \( U \)) or the nextstep operator \( \diamond X \). The nextstep can neither be derived from \( U \) nor from \( U^{\leq t} \) and neither can the bounded or unbounded until be derived from \( \diamond X \).

Thus, we define \( U^{\leq t}, U \) and \( \diamond X \) explicitly as three independent operators (and we will later give three different algorithms to cover these operators).

Intuitively the path formula \( \Phi_1 U^{\leq t} \Phi_2 \) states that \( \Phi_1 \) holds continuously from now on until within at most \( t \) time units \( \Phi_2 \) becomes true. The unbounded operator \( U \Phi_2 \) does not require a certain bound but nevertheless requires \( \Phi_2 \) to become true eventually.

However, the weak until \( (U) \) operator can be derived by using \( U \) via

\[
\begin{align*}
[\Phi_1 U^{\leq t} \Phi_2]_{\geq p} & := \neg [\neg \Phi_2 U^{\leq t} (\neg \Phi_1 \land \neg \Phi_2)]_{\geq (1-p)}, \\
[\Phi_1 U^{\leq t} \Phi_2]_{\leq p} & := \neg [\neg \Phi_2 U^{\leq t} (\neg \Phi_1 \land \neg \Phi_2)]_{\leq (1-p)}, \\
[\Phi_1 U^{\leq t} \Phi_2]_{> p} & := \neg [\neg \Phi_2 U^{\leq t} (\neg \Phi_1 \land \neg \Phi_2)]_{>(1-p)}, \\
[\Phi_1 U^{\leq t} \Phi_2]_{< p} & := \neg [\neg \Phi_2 U^{\leq t} (\neg \Phi_1 \land \neg \Phi_2)]_{<(1-p)}. \\
\end{align*}
\]

1. We identify indexed terminal symbols (here: \( \Phi_1 \) and \( \Phi_2 \)) with terminal symbols \( \Phi \) in order to simplify the PCTL-grammar. The symbol \( a \) represents arbitrary atomic propositions. We assume \( p \in [0, 1] \) and \( t \in \mathbb{N} \). Hence this is an abstract grammar.

2. Informally speaking \( [\Phi_1 U^{\leq t} \Phi_2]_{\preceq p} \) cannot be expressed as nested \( X \) expressions because every \( X \) would have to be enclosed by another \([ \ ]_{\preceq p'}\), which cannot be done because each \( p, p' \), etc. must be constant. Furthermore it is true that \( \neg \Phi \land [\text{true} U^{\leq t} \Phi]_{\preceq p} \equiv [X \Phi]_{\preceq p} \). Nextstep states only about the future, until about the present and the future.
The weak until $\bar{U}$ does not require $\Phi_2$ to become $true$. Either $\Phi_1$ holds for at least the next $t$ time units or $\Phi_2$ becomes $true$ in the next $t$ time units and $\Phi_1$ holds continuously until this happens. The unbounded weak until operator can be defined similarly.

Similar to "always $\Box$" and "eventually $\Diamond$" operators in CTL there are pendants in $PCTL$.

$$[\Diamond^{\leq t}\Phi]_{\leq p} := [trueU^{\leq t}\Phi]_{\leq p},$$

$$[\Box^{\leq t}\Phi]_{\leq p} := \neg [trueU^{\leq t}\neg\Phi]_{\leq p},$$

$$= \neg [\Diamond^{\leq t}\neg\Phi]_{\leq p}.$$  

Again, the definitions are the same for the unbounded versions of these operators. The main difference between $CTL$ and $PCTL$ lies in the extended ability to quantify over paths. While in $CTL$ $\forall\phi$ indicates that the path formula $\phi$ must hold for all paths a $PCTL$ formula like $[\phi]>0.99$ requires the set of paths starting in the current state satisfying $\phi$ to have the probability measure of more than 0.99. The formula $[\Phi_1U^{\leq 10}\Phi_2]>0.5$ states that the set of paths in which $\Phi_1$ will hold continuously until in at most 10 time units $\Phi_2$ will eventually become $true$ has the probability measure of more than 0.5. Some authors write statements like $\Phi_1U_{\geq 10}^{\leq t}\Phi_2$ instead of $[\Phi_1U^{\leq t}\Phi_2]>p$ for the sake of convenience. We omit this for the sake of a clear notation since the $[\ ]_{\leq p}$ quantifier can be applied to a every path formula and not only to $U$ or $\bar{U}$.

Remark 1. $PCTL$ versus $pCTL$

The syntax and semantics of $PCTL$ as defined above follow the work of Hansson and Jonsson [25]. In some papers (for instance [10]) the slightly different language $pCTL$ is used instead of $PCTL$. In $pCTL$ there is no bounded until-operator. To keep this survey consistent we present all results for the bounded until operator $U_{\leq t}$ as well.

Furthergoing relations between the $CTL$-$\forall$ and $-\exists$ quantifier and the $PCTL$-$[\ ]_{\leq p}$ operator will be given after the formal definition of $PCTL$ semantics.

2.3 The Semantics of $PCTL$

While specifications written in $CTL$ or $RTCTL$ syntax are interpreted over transitions systems (also known as Kripke structures), $PCTL$ formulae (and later $PCTL^*$ formulae) are considered in the context of probabilistic systems, be they deterministic (PDS) or nondeterministic (PNS). First of all we attend the deterministic case. For a $PDS$ $T$ we define the satisfaction relation $|=_{PDS}$, that is $|=_{PDS} \subseteq \langle S_T \cup Paths_{s_0\pi} \rangle \times form_{PCTL}$, where $S_T$ denotes the state space of $T$.

Definition 10. $[PCTL$-semantics for $PDS$]

Let $|=_{PDS}$ be the smallest relation s.t. the following constraints are satisfied. We simply write $s |= \Phi$ instead of $(s, \Phi) \in |=_{PDS}$ and $\pi |= \phi$ instead of $(\pi, \phi) \in |=_{PDS}$.
\[ s \models true \]
\[ s \models a \iff a \in L(s) \]
\[ s \models \Phi_1 \land \Phi_2 \iff s \models \Phi_1 \text{ and } s \models \Phi_2 \]
\[ s \models \neg \Phi \iff s \not\models \Phi \]
\[ s \models [\phi]_{strap} \iff \text{prob}_s(\pi \in \text{Paths}_{inf}(s) : \pi \models \phi) \geq p \]
\[ \pi \models \Phi_1 \mathcal{U} \Phi_2 \iff \exists \mathit{t} : \pi \mathcal{U} \Phi_2 \text{ and } \forall j : 0 \leq j < i : \pi^j \models \Phi_1 \]
\[ \pi \models \Phi_1 \mathcal{U} \Phi_2 \iff \exists i \in \mathbb{N} : \pi^i \models \Phi_1 \text{ and } \forall j : 0 \leq j < i : \pi^j \models \Phi_2 \]
\[ \pi \models X \Phi \iff \pi^1 \models \Phi \]

We define the equivalence relation \( \equiv \subset \text{form}_{PCTL} \times \text{form}_{PCTL} \) of two PCTL-formulae \( \Phi_1 \) and \( \Phi_2 \) as

\[ (\Phi_1, \Phi_2) \in \equiv \text{ iff } s \models \Phi_1 \iff s \models \Phi_2 \text{ for all PDS } T \text{ and for all } s \in S_T, \]

and write \( \Phi_1 \equiv \Phi_2 \) instead of \( (\Phi_1, \Phi_2) \in \equiv \).

Remark 2. In order to define the satisfaction relation \( \models \) it is necessary that the set \( \{ \pi \in \text{Paths}_{inf}(s) : \pi \models \Phi \} \) is measurable w.r.t. \( \text{prob}_s \) (see definition 8). This can be shown by structural induction [50].

We now show certain connections between PCTL and CTL.

\( \forall \text{ and } \exists \text{ in CTL versus } \models \text{ in PCTL} \):

Contrary to CTL the syntactical definition of PCTL does neither contain an universal quantification \( \forall \) nor an existential \( \exists \). Nevertheless the following equivalences for CTL formulae on the left and PCTL formulae on the right do hold (where \( a, b \) are atomic propositions):

1. \( \forall (\mathcal{X}a) \equiv [\mathcal{X}a]_{\geq 1} \)
2. \( \exists (\mathcal{X}a) \equiv [\mathcal{X}a]_{\geq 0} \)
3. \( \exists (a \mathcal{U} b) \equiv [a \mathcal{U} b]_{\geq 0} \), but
4. \( \forall (a \mathcal{U} b) \equiv [a \mathcal{U} b]_{\geq 1} \).
5. \( \forall (\mathcal{A}a) \equiv [\mathcal{A}a]_{\geq 1} \) or more general \( \forall (a \mathcal{U} b) \equiv [a \mathcal{U} b]_{\geq 1} \) and
6. \( \exists (\mathcal{A}a) \equiv [\mathcal{A}a]_{\geq 0} \) and hence \( \exists (a \mathcal{U} b) \equiv [a \mathcal{U} b]_{\geq 0} \).

Proofs for (3)-(4) and (6)

(3) If at least one path \( \pi \) exists that fulfills the until formula, the finite prefix \( \pi^i \) of \( \pi \) fulfills \( a \mathcal{U} b \) (for some \( i \in \mathbb{N} \)). It is clear that the basic cylinder of \( \pi^i \) has a measure \( > 0 \) and all paths of \( \Delta(\pi^i) \) satisfy \( a \mathcal{U} b \) as well.

(4) Figure 2 shows a PDS that satisfies the PCTL formula but does not satisfy the CTL formula.

(6) See also figure 2.

In PCTL it would be sufficient to only include \( > \) and \( \geq \) in the syntax, because \( < \) and \( \leq \) can be derived using syntactical transformations. More precisely:

7. \( [\phi]_{> p} \equiv \neg [\phi]_{\leq p} \)
8. \( [\phi]_{\geq p} \equiv \neg [\phi]_{< p} \)
The reason for including $<$ and $\leq$ in the syntax is that the transformation rules (7) and (8) become invalid for the nondeterministic case. Without too much anticipation it should be mentioned here that in order to be able to use the same PCTL-syntax for the deterministic case (this section) and the nondeterministic case (section 3) we include $<$ and $\leq$ but also stress the existence of (7) and (8).

### 2.4 Model Checking of PCTL against a PDS

The basic idea of model checking a PCTL (state) formula $\Phi$ against a probabilistic deterministic system (PDS) $T$ follows the idea of CTL Model Checking à la Clarke, Emerson and Sistla [11] and involves the calculation of satisfaction sets $\text{Sat}(\Phi)$, where $\text{Sat}(\Phi) = \{s \in S_T : s \models \Phi\}$. In order to calculate these sets the syntax tree of $\Phi$ is constructed and the subformulas are processed in a bottom-up manner, more precisely the leaves are labelled with atomic propositions or true, while the inner nodes are labelled with $\neg$, $\land$, $\lceil \cup \rceil_{\text{log}}$, $\lceil \cup \rceil_{\text{log}}$, and $\lceil X \rceil_{\text{log}}$. Nodes labelled with $\neg$ or $\lceil X \rceil_{\text{log}}$ have exactly one son. Other inner nodes have two sons. The algorithm traverses the syntax tree in this (prefix) order and calculates the satisfaction sets recursively (i.e. the syntax tree is not constructed explicitly, see also figure 4).

We now present schemes for calculating solutions for the bounded and unbounded until operator followed by an algorithm that sketches a complete model checking process for PCTL. The calculation of a solution for the nextstep operator ($X$) is presented only in the algorithm and can be understood without any further comment. See also [25].

#### The Bounded Until

The case $[\Phi_1 \cup X^t \Phi_2]_{\text{log}}$, $p$ arbitrary : $P^n(s)$, as defined in the following recursion, is exactly $\text{prob}_s(\Phi_1 \cup X^t \Phi_2)$ \(^3\) that must be calculated in order to decide whether the PCTL-state formula involving a certain probability is satisfied by a certain state $s \in S$.

\(^3\) which here is used as an abbreviation for $\text{prob}_s(\{\pi \in \text{Paths}_{inj}(s) : \pi \models \Phi_1 \cup X^t \Phi_2\})$
(recursion 1)

\[ P^i(s) = \begin{cases} 
1, & \text{if } s \models \Phi_2 \\
0, & \text{if } s \not\models \Phi_1 \text{ and } s \not\models \Phi_2, \\
0, & \text{if } i = 0 \text{ and } s \not\models \Phi_2, \\
\sum_{s' \in S_T} p_{ss'} \cdot P^{i-1}(s') & \text{otherwise}. 
\end{cases} \]

This recursion follows the semantical definition given in definition 10 and states a solution for the bounded until operator. Algorithm 2 performs the calculation of this recursion.

The Unbounded Until (special case)

The case \([\Phi_1 \cup \Phi_2]_{\geq p} \) : We will now see that also a special class of PCTL-formulae with infinite until bounds can be reduced to this scheme easily (we refer to the case \([\Phi_1 \cup \Phi_2]_{\geq 0}\)). Later a recursion is defined which solutions cover arbitrary unbounded until formulae (i.e. \([\Phi_1 \cup \Phi_2]_{\geq p}\)). However because of equivalence (3) (see section 2.3) it is clear that also a conventional graph analysis as performed by an ordinary CTL-model checker could be used here (if \(\Phi_1\) and \(\Phi_2\) are already checked or happen to be atomic propositions). Though the use of a CTL model checker would be the preferable method in this case, we give a proof outline.

Lemma 2. \(s \models [\Phi_1 \cup \Phi_2]_{\geq 0} \Leftrightarrow s \models [\Phi_1 \cup \Phi_2]_{\geq |S_T|\Phi_2} \Leftrightarrow (s \models \exists (\Phi_1 \cup \Phi_2))\).

Proof. "\(\Rightarrow\)" If \(s \models [\Phi_1 \cup \Phi_2]_{\geq 0}\) then \(\pi \in \text{paths}(s) : \pi \models \Phi_1 \cup \Phi_2 \neq \emptyset\). It is clear that because of the finiteness of \(S\) these paths can be shortened by removing cycles such that the bounded until formula holds.

"\(\Leftarrow\)" obvious.

The Unbounded Until (general form)

The case \([\Phi_1 \cup \Phi_2]_{\geq p}\), \(p\) arbitrary : For the solution of this case the calculation schemes as presented above cannot be used. Due to the absence of a finite bound the algorithm could run infinitely and the "trick" with \(U_{\geq |S_T|}\) cannot be applied since the exact calculation of the probability mass function is necessary to decide whether a certain sharp bound \(p > 0\) is reached or not.

A recursion is presented [25] that is based on a partitioning of \(S_T\) into three subsets \(U_0, U_1\) and \(U_7\).

\[
\begin{align*}
S_s &= \text{Sat}(\Phi_2), \\
S_f &= \{ s \in S_T : s \not\in \text{Sat}(\Phi_1) \land s \not\in \text{Sat}(\Phi_2) \}, \\
S_i &= \{ s \in S_T : s \in \text{Sat}(\Phi_1) \land s \not\in \text{Sat}(\Phi_2) \}, \\
U_0 &= S_f \cup \{ s \in S_i : \text{there exists no path in } S_i \text{ from } s \text{ to any } s' \in S_s \}, \\
U_1 &= S_s \cup \{ s \in S_i : \text{the measure of reaching a state in } S_s \text{ through } S_i \text{ starting in } s \text{ is } 1 \}, \\
U_7 &= S \setminus (U_1 \cup U_0),
\end{align*}
\]
These sets can be calculated in the following way:

$S_s, S_f, S_i$: These sets can be calculated by investigating the labelling, respectively the satisfaction sets of the maximal proper subformulae for each state $s \in S_T$.

**Preliminary step:** Remove every edge $(s, s') \in T$ for each $s \in S_f \cup S_s$.

$U_0$: Perform a backward search starting in $S_s$. Obviously every state in $S \setminus U_0$ will be visited, which yields $U_0$.

$U_1$: Perform (with $U_0$ at hand) a backward search starting in $U_0$. Now every state in $S \setminus U_1$ is visited, which yields $U_1$.

$U_?$: With $U_1$ and $U_0$, calculate $U_? = S \setminus (U_1 \cup U_0)$.

With these sets the following recursion describes the measure for the unbounded until operator.

(recursion 2)

$$P^\infty(s) = \begin{cases} 
1, & \text{if } s \in U_1 \\
0, & \text{if } s \in U_0, \\
\sum_{s' \in S_T} p_{ss'} \cdot P^\infty(s') & \text{otherwise}
\end{cases}$$

This recursion is a linear equation system, which has an unique solution [25, 15].

$$x_s = \sum_{s' \in U_?} p_{ss'} \cdot x_{s'} + \sum_{s'' \in U_1} p_{ss''}, s \in U_?$$

This linear equation system can be solved in polynomial time for instance using Gaussian elimination. However, for large probability matrices iterative methods like the Jacobi- or the Gauss-Seidel-method might be better.
Remark 3.
The until operator of CTL has a least fixpoint semantic, i.e. \( \text{Sat}(\exists \Phi \cup \Phi_2) \) and \( \text{Sat}(\forall \Phi \cup \Phi_2) \) are the least fixed points of certain monotone higher-order operators. For PCTL, a similar least fixed point characterization of \( \mathcal{U} \) can be established (see e.g. [3]):
The probability vector \( (q_s)_{s \in S_T} \) where \( q_s = P^\infty(s) \) is the least solution in \(([0, 1]^{\vert S_T \vert})\) of the equation system

\[
x_s = 0 \text{ if } s \in U'_0 \\
x_s = 1 \text{ if } s \in U'_1 \\
x_s = \sum_{s' \in U'_1} p_{ss'} \cdot x_{s'} + \sum_{s'' \in U'_1} p_{ss''} \text{ if } s \in U'_2
\]

where \( U'_0, U'_1, U'_2 \) are arbitrary sets with \( U'_0 \subseteq U_0, U'_1 \subseteq U_1 \subseteq \text{Sat}(\Phi_2) \) and \( U'_1 \subseteq S_T \setminus (U'_0 \cup U'_1) \). In order to obtain a unique solution the condition \( U'_0 = U_0 \) is needed. The reason is that otherwise, e.g. for states \( s \in S_T \setminus (\text{Sat}(\Phi_1) \cup \text{Sat}(\Phi_2)) \) with \( p_{ss'} = 1 \), we have the equation \( x_s = x_s \) which, of course, has no unique solution.

The algorithm

Pseudocode for model checking PCTL against a PDS is presented (algorithm 1 and algorithm 2) that uses the connections stated in the paragraphs before. In algorithm 2 we are not interested in particular if the starting state \( s \in S_T \) satisfies the PCTL specification. Instead the satisfaction set \( \text{Sat}(\Phi) \) is calculated that contains all states \( s \in S_T \) s.t. \( s \models \Phi \). In addition to that we need a stub algorithm (algorithm 1) which is called with the starting state and which’s only task is to check whether it is true or not that the starting state is contained in \( \text{Sat}(\Phi) \) (which was calculated by algorithm 2).

In algorithm 2 it is stated (implicitly due to the recursive execution) that a syntax tree of \( \Phi \) is built and processed in bottom up manner. This assures an efficient complexity for the processing of the subformulas and is illustrated in figure 4. The syntax tree is built according to the PCTL-grammar. Atomic propositions will always be leafs of this tree, the \( \text{Sat} \) sets are calculated for these leafs. The next inner nodes to be processed will either be Boolean combinations (i.e. \( \wedge, \vee \) or \( \neg \)) or nextstep- or until-expressions. \( \text{Sat} \) sets for these are calculated according to the cases in the algorithm.

The Complexity of PCTL model checking against a PDS

We now outline the complexity of the model checking algorithm for checking a PCTL formula \( \Phi \) against a PDS. Given a PDS \( \mathcal{T} = (M, AP, L, T), M = (S, T, p) \), we give asymptotic complexity results. Obviously, the number of sub-formulae to be checked is \( \leq \text{length}(\Phi) \).
\[ \Phi = sending \rightarrow [\Diamond \leq 5\text{ sent}]_{0.99} \]
\[ \equiv \neg sending \lor [\Diamond \leq 5\text{ sent}]_{0.99} \]

**Fig. 4.** Syntax tree example.

**Algorithm 1** PCTL\_MODELCHECK(\( \Phi, T \))

**Input:** PDS \( T \), PCTL formula \( \Phi \), \( s \in S_T \)

**Output:** truth value of \( \bar{s} \models_{PDS} \Phi \)

1. calculate \( Sat(\Phi) \) with algorithm 2.
2. **IF** \( s \in Sat(\Phi) \) **THEN**
   - return true
3. **ELSE**
   - return false
Algorithm 2 Sat(\(\Phi\))

Input: PCTL state formula,

Output: Set of all \(s \in S\) that satisfy \(\Phi\)

CASE \(\Phi\) is

true : return \(S_T\);

\(a\) : return \(\{s \in S_T : a \in L(s)\}\);

\(\Phi_1 \land \Phi_2\) : return \(Sat(\Phi_1) \cap Sat(\Phi_2)\);

\(\neg \Phi'\) : return \(S_T \setminus Sat(\Phi')\);

\([\chi \Phi']_s\) : calculate \(Sat(\Phi')\) and return \(\{s \in S_T \mid \sum_{s' \in Sat(\Phi')} p_{ss'} \geq \}\);

\([\Phi_1 U^{\leq t} \Phi_2]_s\) : calculate \(Sat(\Phi_1)\) and \(Sat(\Phi_2)\);

\(\forall s \in S_T : P^0(s) = \begin{cases} 1 & \text{if } s \in Sat(\Phi_2), \\ 0 & \text{otherwise} \end{cases}\)

FOR \(i = 1\) to \(t\) DO

\(\forall s \in S_T : P^i(s) = \begin{cases} 0, & \text{if } s \notin Sat(\Phi_1) \text{ and } s \notin Sat(\Phi_2), \\ 1, & \text{if } s \in Sat(\Phi_2), \\ \sum_{s' \in S_T} p_{ss'} \cdot P^{i-1}(s') \text{ otherwise}. \end{cases}\)

OD;

\(\forall s \in S_T : P^\infty(s) = \begin{cases} 0, & \text{if } s \notin Sat(\Phi_1) \text{ and } s \notin Sat(\Phi_2), \\ 1, & \text{if } s \in Sat(\Phi_2), \\ \sum_{s' \in S_T} p_{ss'} \cdot P^{i-1}(s') \text{ otherwise} \end{cases}\)

RETURN \(\{s \in S_T : P^\infty(s) \geq \}\);

\([\Phi_1 U \Phi_2]_{>0}\) : calculate \(Sat(\Phi_1)\) and \(Sat(\Phi_2)\) and do conventional graph analysis;

RETURN \(\{s \in S_T : s \models \exists(\Phi_1 U \Phi_2)\}\);

\([\Phi_1 U \Phi_2]_{s\omega}\) : calculate \(Sat(\Phi_1)\) and \(Sat(\Phi_2)\) and solve linear equation system;

RETURN \(\{s \in S_T : P^\infty(s) \geq \}\).

END CASE
For the case that $\Phi'$ is an atomic proposition, its negation or a boolean combination of them, the satisfaction set $\text{Sat}(\Phi')$ can be computed in time $O(|S|)$.

- If $\Phi'$ is a next-step expression $[X\Phi']$ it can be checked in time $O(|S| + |T|)$ (where we assume a sparse matrix representation).
- The case $\Phi' = \phi_1 U \leq t \phi_2$ can be checked in time $O(|V| \cdot |T| \cdot t)$.
- The case $\Phi' = \phi_1 U \phi_2$ can be checked by computing the sets $U_0, U_1$ and $U_t$ in time $O(|S| + |T|)$ each and then solving a linear equation system of size $|S| \times |S|$ which is possible to do in time $O(poly(|S|))$.
- The recursion tree of algorithm 2 (which can be seen as building and processing the systamtree of $\Phi$) requires $O(length(\Phi))$ steps.

**Theorem 1.** Let $T$ be a PNS and $\Phi$ a PCTL state formula over the set of atomic propositions of $T$. Then $\text{Sat}(\Phi)$ can be computed in time $O(poly(|S|) \cdot length(\Phi))$.

**Proof.** The correctness of theorem 1 follows from the statements about the complexities made before.

### 2.5 The Syntax and semantics of PCTL*

We now introduce the logic PCTL* and explain how to model check a PDS against a PCTL*-formula. Throughout this section let $T = (M, AP, L, \bar{s})$ be a PDS with $M = (S, T, p)$.

Like standard CTL we can extend PCTL to a richer logic PCTL* which allows the negation and conjunction of path formulae and also the combination of temporal modalities. In addition, every state formula is as well a path formula.

**Definition 11. [PCTL* Syntax]**

Given the set of atomic propositions AP, the syntax of PCTL*-formulae over AP is defined by the following grammar:

- **PCTL*-state formulae:
  $\Phi ::= true \mid a \mid \Phi_1 \land \Phi_2 \mid \neg \Phi \mid [\phi]_{[0, p]}$

- **PCTL*-path formulae:
  $\phi ::= \neg \phi \mid \phi_1 \land \phi_2 \mid \Phi \mid \phi_1 U \leq t \phi_2 \mid \phi_1 U \phi_2 \mid X\phi$

where $a \in AP$, $t \in \mathbb{N}$, $p \in [0, 1] \subset \mathbb{R}$ and $\geq \in \{\geq, >, <\}$.

With $\text{State}_{PCTL*} = \{\Phi : \Phi$ is a PCTL* state formula\} we denote the set of all PCTL* state formulae and with $\text{Path}_{PCTL*} = \{\phi : \phi$ is a PCTL* path formula\} we denote the set of all PCTL* path formulae for a fixed set AP of atomic propositions. Observe that $\text{State}_{PCTL*} \subset \text{Path}_{PCTL*}$ holds.

For the PDS $T$ we define the satisfaction relation $\models^*_\text{PDS}$, which is a relation on $(S \cup \text{Paths}_{inf}) \times \text{Path}_{PCTL*}$.
Definition 12. [PCTL*-Semantics for Probabilistic Deterministic Systems]

Let $\models_{PDT}^*$ be the smallest relation on $\langle S \cup Paths_{inf} \rangle \times Paths_{PCTL^*}$ s.t. for $a \in AP$, $\Phi, \Phi_1, \Phi_2 \in State_{PCTL^*}$, $\phi, \phi_1, \phi_2 \in Path_{PCTL^*}$ and $s \in S$:

$s \models true$
$s \models a \iff a \in L(s)$
$s \models \Phi_1 \land \Phi_2 \iff s \models \Phi_1 \land s \models \Phi_2$
$s \models \neg \Phi \iff \neg s \models \Phi$
$s \models [\phi]_{\leq p} \iff \text{prob}_s(\{\pi \in Paths_{inf}(s) : \pi \models \phi\}) \geq p$

\begin{align*}
\pi \models \phi_1 \land \phi_2 & \iff \pi \models \phi_1 \land \pi \models \phi_2 \\
\pi \models \neg \phi & \iff \pi \not\models \phi \\
\pi \models \Phi & \iff \pi \models \Phi \\
\pi \models \phi_1 U^t \phi_2 & \iff \exists \ i \leq t \text{ such that } \pi|_i \models \phi_2 \text{ and } \forall j : 0 \leq j < i : \pi|_j \models \phi_1 \\
\pi \models \phi_1 U \phi_2 & \iff \exists \ i \in \mathbb{N} \text{ such that } \pi|_i \models \phi_2 \text{ and } \forall j : 0 \leq j < i : \pi|_j \models \phi_1 \\
\pi \models X \phi & \iff \pi|_{i+1} \models \phi
\end{align*}

Note, that the definition of the semantics requires that the set $\{\pi \in Paths_{inf}(s) : \pi \models \phi\}$ is measurable for a $PCTL^*$ formula $\phi$. Like for $PCTL$ formulae, this can be shown by structural induction (see remark 2).

Remark 4.

Note, that for a $PCTL^*$-path formula the following equivalences hold, since Paths_{inf} is the disjoint union of $\{\pi \in Paths_{inf} : \pi \models \phi\}$ and $\{\pi \in Paths_{inf} : \pi \models \neg \phi\}$.

- $s \models [\phi]_{< p} \iff s \models [\neg \phi]_{(1-p)}$
- $s \models [\phi]_{\leq p} \iff s \models [\neg \phi]_{1-(1-p)}$

Due to this fact, it is sufficient to consider formulae which do not make use of $[.]_{< p}$ and $[.]_{\leq p}$. Note however, that the above equivalences can not be applied for $PCTL$ formulae, since it is not allowed to negate $PCTL$-path formulae.

As in the nonprobabilistic case, one could also define the logic $PCTL^+$, which extends $PCTL$ by negation and conjunction of path formulae, but does not allow the combination of temporal modalities (e.g. $\phi_1 U \phi_2$, where $\phi_1$ and $\phi_2$ are path formulae). In contrast to the nonprobabilistic case, where $CTL^+$ is not more expressive than $CTL$, we believe that $PCTL^+$ is strictly more expressive than $PCTL$. We only give an informal argument and show where the transformation method from $CTL^+$ to $CTL$ fails in the probabilistic case. Consider the $CTL^+$ formula $\Phi = \exists (\Diamond a \land \Diamond b)$. Then the following equivalence holds:

$\exists (\Diamond a \land \Diamond b) \equiv \exists (a \land \exists \Diamond b) \lor \exists (b \land \exists \Diamond a)$,

where the formula on the right hand side is a $CTL$ formula. Considering only one path (due to the existential quantification), the above equivalence is easy to

\footnote{Observe that we use the notation $s \models \Phi$ (resp. $\pi \models \phi$) instead of $(s, \Phi) \in \models_{PDT}^*$ (resp. $(\pi, \phi) \in \models_{PDT}^*$).}
accomplish. But in the probabilistic setting, we have the following problem:
\[ \langle \Diamond a \land \Diamond b \rangle_{\geq p} \neq \langle \Diamond (a \land \Diamond b) \rangle_{\geq p} \lor \langle \Diamond (b \land \Diamond a) \rangle_{\geq p}, \]
whatever might be in place for the question marks. Even the following idea with an infinite disjunction of PCTL formulae does not work:
\[ \langle \Diamond a \land \Diamond b \rangle_{\geq p} \neq \bigvee_{p_1, p_2+p_3+p_4 \geq p} [-b \mathcal{U}(a \land \Diamond b)_{\geq p_2}]_{\geq p_1} \land [-a \mathcal{U}(b \land \Diamond a)_{\geq p_3}]_{\geq p_4}. \]
Note that the infinite disjunction is not a PCTL formula, since PCTL formulae are always finite (so the \( \neq \) is not really appropriate in this case). Moreover do we believe that there is no alternative way to express \( \langle \Diamond a \land \Diamond b \rangle_{\geq p} \) in an equivalent PCTL formula.

For the sake of completeness we shortly describe the logic LTL since we will need it later.

**Definition 13. [LTL-Syntax]**

Given the set of atomic propositions \( AP \), LTL-formulae over \( AP \) are PCTL*-path formulae given by the following grammar:

\[
LTL \text{ formulae:} \\
\phi ::= true \mid a \mid \neg \phi \mid \phi_1 \land \phi_2 \mid \phi_1 \mathcal{U} \phi_2 \mid \phi_1 \mathcal{F} \phi_2 \mid X \phi
\]

where \( a \in AP \) and \( t \in \mathbb{N} \).

We define the language \( L_\omega(\phi) \) of a LTL formula \( \phi \) over \( AP \) to be the set of infinite words \( w \) over \( 2^{AP} \) such that \( w \models \phi \), assuming \( L(x) = x \ \forall x \in 2^{AP} \). Note that for a path \( \pi \) the following holds:

\[ \pi \models \phi \text{ if and only if } trace(\pi) \in L_\omega(\phi). \]

**2.6 Model Checking of PCTL* against a PDS**

There are different approaches to PCTL* model checking against deterministic system (see e.g. [3, 13, 51]). We follow the automata theoretic approach since we will do the same in section 3.3 where we discuss nondeterministic systems. Given a state formula \( \Phi \in State_{PCTL} \), we want to compute the set \( \text{Sat}(\Phi) \). To do so, we proceed in the same way as with CTL* formulae (see [29]).

As with PCTL formulae, we first create the parse tree of our given formula and then work from the bottom to the top using satisfaction sets for all subformulae. Having a look at the above defined semantics tells us that conjunction (resp. negation) are just the intersection (resp. the complement) of satisfaction sets of subformulae\(^5\). The terminal cases are also easy to handle. That leaves us with the

\[^5\] \( \text{Sat}(\Phi_1 \land \Phi_2) = \text{Sat}(\Phi_1) \cap \text{Sat}(\Phi_2) \) and \( \text{Sat}(\neg \Phi) = S \setminus \text{Sat}(\Phi) \)
case $\Phi = [\phi]_{\omega^{\geq}}$. We assume that we have already computed the satisfaction sets for all maximal state subformulae $\gamma_1, \ldots, \gamma_n$ of $\phi$ and have labelled the states of $S$ appropriately with new atomic propositions $r_1, \ldots, r_n$. Let

$$\phi' = \phi \{ \gamma_1 / r_1, \ldots, \gamma_n / r_n \}$$

be the formula we get from $\phi$ by replacing each occurrence of $\gamma_i$ by $r_i$, $1 \leq i \leq n$. Then $\phi'$ is a $LTL$ formula over the atomic propositions $r_1, \ldots, r_n$. In order to decide whether $s \models_{PDS} [\phi']_{\omega^{\geq}}$, we have to compute

$$\text{prob}_{\pi}(\{ \pi \in \text{Paths}_{s, t}(s) : \pi \models \phi \}).$$

This can be done by using the standard $\omega$-automaton approach (see e.g. [48, 52]). A $\omega$-automaton accepts infinite words over a given alphabet. In the probabilistic setting a kind of determinism is needed. Here we use deterministic Rabin automata.

**Definition 14. [Deterministic Rabin Automaton]**

A deterministic Rabin automaton is a tuple

$$A = (\Sigma, Q, q, \rho, \alpha),$$

where

- $\Sigma$ is a finite alphabet,
- $Q$ is a finite set of states,
- $q \in Q$ is an initial state,
- $\rho : Q \times \Sigma \rightarrow Q$ is a transition function and
- $\alpha \subseteq 2^Q \times 2^Q$ is an acceptance condition.

**Definition 15. [Run, Limit and $\omega$-satisfaction]**

Given a deterministic Rabin automaton $A = (\Sigma, Q, q, \rho, \alpha)$ and an infinite word $w = a_1, a_2, \ldots \in \Sigma^\omega$ over $\Sigma$ we call the unique sequence $r = q, q_1, q_2, \ldots$ with

$$q_i = \rho(q_{i-1}, a_i) \quad (q_0 = q)$$

the run of $A$ over $w$.

We define the limit of a run $r = q, q_1, q_2, \ldots$ as

$$\lim(r) = \{ q : q = q_i \text{ for infinitely many } i \}'s \}.$$

We say a subset $X \subseteq Q$ satisfies $\alpha$ if and only if

$$\exists (L, U) \in \alpha : L \cap X \neq \emptyset \land U \cap X = \emptyset.$$

We say a run $r$ satisfies $\alpha$ if and only if $\lim(r)$ satisfies $\alpha$.

Observe that Rabin acceptance can be expressed in a $LTL$ formula, i.e. $r$ satisfies $\alpha$ iff $r$ satisfies the $LTL$ formula

$$\forall (L, U) \in \alpha (\Box L \land \Diamond \neg U).$$

$^a r_i \in L(s)$ iff $s \in \text{Sat}(\gamma_i)$, where $AP$ is extended by $\{r_1, \ldots, r_n\}$
We now define the language of a deterministic Rabin automaton.

**Definition 16.** $[L_\omega(A)]$

Let $A = (\Sigma, Q, \bar{q}, \rho, \alpha)$ be a deterministic Rabin automaton and $w \in \Sigma^\omega$. Let $r$ be the run of $A$ over $w$. We say $A$ accepts $w$ if and only if $r$ satisfies $\alpha$. We call the set

$$L_\omega(A) = \{w \in \Sigma^\omega : A \text{ accepts } w\}$$

the language of $A$.

We now state a useful lemma (see [48, 52, 51, 44]).

**Lemma 3.** [Rabin automaton for a LTL formula]

Given a LTL formula $\phi$ over $AP$, a Deterministic Rabin automaton $A$ with the alphabet $2^{AP}$ can be constructed such that

$$L_\omega(\phi) = L_\omega(A).$$

Remember that we want to compute the value

$$\text{prob}_s(\{\pi \in \text{Paths}_{inj}(s) : \pi \models \phi'\}),$$

where $\phi'$ is a LTL formula over the extended set $AP$ of atomic propositions. We first construct a deterministic Rabin automaton $A = (\Sigma, Q, \bar{q}, \rho, \alpha)$ with $L_\omega(\phi') = L_\omega(A)$. We then build a product Markov chain $T \times A$ for $T$ and $A$ by the following:

- $T \times A = (S \times Q, T', p')$ with
  - $p'(\langle s, q \rangle, \langle s', q' \rangle) = p_{ss'}$ if $q' = \rho(q, L(s))$ and 0 otherwise
  - $T' = \{\langle \langle s, q \rangle, \langle s', q' \rangle \rangle : p'(\langle s, q \rangle, \langle s', q' \rangle) \neq 0\}$.

It is easy to see that there is a one-to-one correspondence between the paths of $T$ and those of $T \times A$ by path-lifting. In addition, taking a path $\pi$ of $T$, lifting it to a path $\pi'$ of $T \times A$ and then reducing it to its second component, gives the run of $A$ over trace($\pi$). So $T \times A$ also keeps track whether trace($\pi$) will be accepted by $A$ or not, i.e. whether $\pi$ satisfies $\phi'$ or not. Taking this into account it is easy to show that

$$\text{prob}_{T}^T(\{\pi \in \text{Paths}_{inj}(s) : \pi \models \phi'\}) = \text{prob}_{T \times A}^{(s, \bar{q})}(\{\pi' \text{ path in } T \times A : \pi' \text{ satisfies } \alpha'\}),$$

where $\alpha'$ is the lifted accepted condition from $A$, i.e.

$$\alpha' = \{(S \times L, S \times U) : (L, U) \in \alpha\}.$$ 

Let $\text{Acc}$ be the union of the ergodic sets of $T \times A$ that satisfy $\alpha'$. Using lemma 1 about ergodic sets, it follows that

$$\text{prob}_{T \times A}^{(s, \bar{q})}(\{\pi' \text{ path in } T \times A : \pi' \text{ satisfies } \alpha'\}) = \text{prob}_{(s, \bar{q})}^{T \times A}(\{\pi' \text{ path in } T \times A : \pi' \text{ reaches } \text{Acc}\}).$$
The right side of this equation equals

\[ \text{prob}_T(\{ \pi' \text{ path in } T \times A \mid \pi' \models \diamond \text{acc} \}) \]

when exactly the states \( \in \text{Acc} \) are labelled with \( \text{acc} \) and can therefore be computed by the algorithms introduced in the \( \text{PCTL} \) section 2.4. The following flow chart (figure 5) sketches the main ideas:

As a closing remark we want to mention that the size of the constructed automaton \( \mathcal{A} \) is doubly exponential in the size of the formula \( \phi' \). And the time needed to compute \( \text{prob}_T(\{ \pi \in \text{Paths}_{\text{inf}}(s) : \pi \models \phi \}) \) is doubly exponential in \( |\phi| \). However, in [15] a different approach is discussed, which is only single exponential in \( |\phi| \). In addition, both methods are polynomial in the size of the system. (See the article by B. Bollig and M. Leuker in this volume.)

3 Validation of Nondeterministic Probabilistic Systems

In section 2 methods were established to show how to model check \( \text{PCTL} \) and \( \text{PCTL}^* \) against a \text{PDS}. We now move on to probabilistic nondeterministic systems that involve a set of probability distributions per transition rather than only one as in the deterministic case. In non-probabilistic systems nondeterminism can be used to describe input behaviour from outside the system (e.g. user input) or certain fault possibilities. Also the interleaving behaviour of asynchronous parallel processes can be expressed using nondeterminism. This carries over to the
probabilistic setting, in which also underspecification can be expressed with nondeterminism. In the nondeterministic case schedulers are introduced that pick the distributions as the execution of a nondeterministic system goes along. These probabilistic nondeterministic systems essentially are state-labelled Markov Decision Processes (MDPs).

3.1 Nondeterministic Probabilistic Systems

We now define nondeterminism in the probabilistic context. Several types of nondeterministic systems were introduced in [50, 24, 26, 46] and [10]. We follow here the approach of [10].

**Definition 17. [Probabilistic Nondeterministic System (PNS)]**

A probabilistic nondeterministic system is a tuple

$$T_{PNS} = (S, \text{Steps}, AP, L, \bar{s}),$$

where

- $S$ is a finite set of states,
- $\text{Steps}$ is a function that assigns to each state $s \in S$ a finite, non-empty set of probability distributions on $S$, i.e.

  $$\text{Steps} : S \rightarrow 2^{\text{Distr}(S)},$$

  such that $1 \leq |\text{Steps}(s)| < \infty \quad \forall s \in S.$
- $AP$ is a finite set of atomic propositions,
- $L$ is a labelling function $L : S \rightarrow 2^{AP}$ that labels any state $s \in S$ with those atomic propositions that are supposed to hold in $s$ and
- $\bar{s} \in S$ is the starting state.

Similar to section 2.1 for the rest of this chapter we simply write $T$ instead of $T_{PNS}$.

Thus the main difference between definition 4 of a PDS and the definition of a PNS is, that there is not only one transition distribution per state but a set of distributions and a function $\text{Steps}$ that yields them for each state. Intuitively, the set $\text{Steps}(s)$ represents the non-deterministic alternatives in state $s$. Having resolved the nondeterminism in a state $s$, i.e. having chosen a $\mu \in \text{Steps}(s)$, the process itself resolves the probabilistic choice by selecting some state $s'$ with the probability $\mu(s')$. We refer to the elements of $\text{Steps}(s)$ as the transitions of $s$.

We now explain how a path is defined in a PNS.

**Definition 18. [Path in a PNS]**

Let $T = (S, \text{Steps}, AP, L, \bar{s})$ be a probabilistic nondeterministic system. We define a path of $T$ to be a (finite or infinite) sequence

$$\pi = s_0 \overset{\mu_1}{\rightarrow} s_1 \overset{\mu_2}{\rightarrow} s_2 \ldots$$

s.t. for all $i$ under consideration : $s_i \in S$, $\mu_{i+1} \in \text{Steps}(s_i)$ and $\mu_{i+1}(s_{i+1}) > 0$. 

The definitions of the length of a path, of first(\(\pi\)), last(\(\pi\)), \(\pi^k\), and \(\pi^k\) and of \(\text{Paths}_{\text{fin}}\), \(\text{Paths}_{\text{inf}}\) (resp. \(\text{Paths}_{\text{fin}}(s), \text{Paths}_{\text{inf}}(s)\)) carry over from the deterministic case (see definition 5). If \(k < |\pi|\), we put \(\text{step}(\pi, k) = \mu_{k+1}\). As for deterministic Rabin automata, given an infinite path \(\pi\), we denote by \(\lim(\pi)\) the set of states that occur infinitely often in \(\pi\).

But how is the nondeterminism resolved? We give the definition of a scheduler (sometimes called strategy, adversary or policy) that decides, based on the past history of the system, which possible step to perform next.

**Definition 19. [Scheduler]**

Let \(T = (S, \text{Steps}, AP, L, \bar{s})\) be a probabilistic nondeterministic system. A scheduler of \(T\) is a function \(B\) mapping every finite path \(\omega\) of \(T\) to a distribution \(B(\omega) \in \text{Steps}(\text{last}(\omega))\).

That means, after the process described by the \(PNS\) performed the first \(|\omega|\) steps, the scheduler \(B\) chooses the next transition to be \(\mu = B(\omega)\), thus resolving the nondeterminism. So if a system behaves according to a scheduler \(B\) and has followed the sequence \(\omega = s_0, s_1, \ldots, s_n\) so far, then it will be in state \(s\) in the next step with probability

\[B(\omega)(s)\]

We denote the set of infinite paths that comply with a given scheduler \(B\) with \(\text{Paths}_{\text{inf}}^B\), i.e.

\[\text{Paths}_{\text{inf}}^B = \{\pi \in \text{Paths}_{\text{inf}} : B(\pi^i) = \text{step}(\pi, i) \; \text{i} = 0, 1, 2, \ldots\}\]

We call a scheduler \(B\)

simple, iff \(B(\omega) = B(\text{last}(\omega)) \forall \text{finite path } \omega\),

i.e. \(B\) is history independent.

For a state \(s\) to satisfy a \(\text{PCTL}^*\) state formula of the type \([\phi]_{\geq}^7\), we need to ensure that starting in \(s\), the given system produces a path satisfying \(\phi\) with a probability \(\geq\) for all schedulers under consideration.

We therefore define for each \(s \in S\) and for each scheduler \(B\) a probability space on the set of infinite paths starting in \(s\). The basic cylinders of a \(PNS\) are defined exactly as the basic cylinders of a \(PDS\), see definition 7. So we can give the definition of the needed probability spaces.

**Definition 20. [Probability space of a \(PNS\)]**

Given a \(PNS\) \(T = (S, \text{Steps}, AP, L, \bar{s})\), a scheduler \(B\) and \(s \in S\), we define a probability space

\[\Psi^B_s = (\Delta(s), \Delta^s, \text{prob}^B_s)\]

such that

- \(\Delta^s\) is the \(\sigma\)-algebra generated by the empty set and the basic cylinders that are contained in \(\Delta(s)\).

\(^2\) Remember, that \(\geq, >, \leq, <\) are binary relations.
- \( \text{prob}^B \) is the uniquely induced probability measure which satisfies the following: \( \text{prob}^B_\omega(\Delta(s)) = 1 \) and for all basic cylinders \( \Delta(\omega) \subseteq \Delta(s) \) with \( \omega = s_0, s_1, \ldots, s_n \):

\[
\text{prob}^B_\omega(\Delta(\omega)) = \text{prob}^B_\omega(\Delta(s_0, s_1, \ldots, s_n)) = \prod_{i=0}^{\vert \omega \vert - 1} B(s_i, \ldots, s_i)(s_{i+1}).
\]

Note that the underlying sigma algebra is the same for all schedulers.

**Remark 5.**

To get the above probability space \( \Psi^B_\omega \) for some \( s \in S \) and some scheduler \( B \) one can also consider the markov chain

\[ M^B_\omega = (S^B_\omega, T^B_\omega, p^B_\omega), \]

where

- \( S^B_\omega = \text{Paths}_{fin} \cap \Delta(s) \) and

for all \( \omega, \omega' \in S^B_\omega \times S^B_\omega \)

- \( p^B_\omega(\omega, \omega') = B(\omega)(\text{last}(\omega')) \), if \( \omega = \omega' \uparrow \vert \omega' \vert - 1 \) and 0 otherwise.
- \( (\omega, \omega') \in T^B_\omega \iff p^B_\omega(\omega, \omega') > 0. \)

If we now identify \( \omega \in \text{Paths}_{fin} \) with \( \omega^B_\omega \), where \( (\omega^B_\omega)^i = \omega^i \), \( i = 0, 1, \ldots, \vert \omega \vert \) and \( \vert \omega^B_\omega \vert = \vert \omega \vert \), we get that \( \text{prob}^B_\omega(\Delta(\omega)) \) equals the measure of \( \Delta(\omega^B_\omega) \) in the markov chain \( M^B_\omega \).

Now we have everything on hand to define the semantics of \( \text{PCTL}^* \) formulae over a \( PNS \) with respect to a given set of schedulers. We follow the work of [10]. For the rest of this section let \( T = (S, \text{Steps}, \text{AP}, L, \bar{s}) \) be a \( PNS \) and let \( \text{Sched} \) be a nonempty set of schedulers of \( T \).

**Definition 21.** [\( \text{PCTL}^* \)-Semantics for Probabilistic Nondeterministic Systems]

Let \( \models_{\text{Sched}} \) be the smallest relation on \( (S \cup \text{Paths}_{inf}) \times \text{Path}_{\text{PCTL}^*} \) s.t. for \( a \in \text{AP}, \Phi, \Phi_1, \Phi_2 \in \text{State}_{\text{PCTL}^*}, \phi, \phi_1, \phi_2 \in \text{Path}_{\text{PCTL}^*} \) and \( s \in S \):

---

8 Note that \( s_0 = s \).
9 The state set of \( M^B_\omega \) is countable. Nevertheless do the definitions given in section 2.1 for finite markov chains also work here.
Again it is required, that the set \( \{ \pi \in \text{Paths}_{\inf}^B : \pi \models Sched \phi \} \) is measurable for a PCTL* formula \( \phi \) and a scheduler \( \mathcal{B} \), which follows from the analogical fact in the deterministic setting and remark 5 (or can be shown by structural induction).

So in order to model check a formula of the kind \( [\phi]_{\geq} \) for a state \( s \), we have to verify that for all schedulers \( \mathcal{B} \in Sched \) under consideration the value \( \text{prob}_s^B(\{ \pi \in \text{Paths}_{\inf}^B(s) : \pi \models Sched \phi \}) \) is \( \approx p \).

Remark 6.
Note that for a PNS and a PCTL formula \( \phi \), we cannot decide whether \( s \models Sched [\phi]_{\leq} \) with \( (\leq \in \{ \leq, < \}) \) by just considering PCTL formulae of the type \( s \models Sched [\phi']_{\leq} \) with \( (\geq \in \{ \geq, > \}) \). This was possible in the case of PDS (see equivalences 7 and 8 in section 2.3), but becomes impossible here, because the semantics quantifies over all schedulers.

In contrary to that, it suffices for PCTL* formulae to choose \( \approx \) from \( \{ \geq, > \} \) because of remark 4.

What kind of sets \( Sched \) are we interested in? There are two different sets of schedulers we will focus on, the set \( Sched_{\text{all}} \) of all schedulers and the set \( Sched_{\text{fair}} \) of fair schedulers, which will be defined in the following. First we give a definition of a fair path. For simplicity, we restrict our attention to strong fairness for all transitions. Other notions of fairness are considered in e.g. [50, 40, 42].

Definition 22. [Fairness of an infinite path]
Let \( T = (S, \text{Steps}, \text{AP}, L, s) \) be a PNS and \( \pi \) an infinite path of \( T \). \( \pi \) is called fair, iff the following holds:

\[
\forall s \in \text{lim}(\pi) : \forall \mu \in \text{Steps}(s) : |\{j : \pi^j = s \land \text{step}(\pi, j) = \mu\}| = \infty
\]

We denote the set of fair paths by \( \text{Paths}_{\text{fair}} \).

\(^{10}\) Note, that \( \text{Paths}_{\text{fair}} \subseteq \text{Paths}_{\inf} \).
That means a path $\pi$ is fair, if and only if for each state $s$ occurring infinitely often in $\pi$, each nondeterministic alternative in $\text{Steps}(s)$ is taken infinitely often in $\pi$ (at $s$). For a scheduler $B$ to be fair we require the set of fair paths to have measure 1.

**Definition 23. [Fair Scheduler]**

Let $T = (S, \text{Steps}, AP, L, s)$ be a PNS and $B$ be a scheduler for $T$. We call $B$ fair, if and only if $\text{prob}_{B}^{\pi}(\text{Path}^{\pi}_{\text{fair}}(s) \cap \text{Path}_{\text{fair}}) = 1$.

Note, that in the following we will write $|=_{\text{all}}$ instead of $|=_{\text{Sched}_{\text{all}}}$ and $|=_{\text{fair}}$, instead of $|=_{\text{Sched}_{\text{fair}}}$.

We now give an example of a PNS. We depict a PNS as follows. We use ellipses for the states. Thick arrows stand for the outgoing transitions from a state. A transition $\mu \in \text{Steps}(s) \setminus \{\mu_i^t : t \in S\}$ is represented by a thick arrow that ends in a small circle, representing the probabilistic choice. We use directed thin arrows leading from the circle of a probabilistic choice to the possible successor states (i.e. all states $t$ where $\mu(t) > 0$). A distribution $\mu_i^t \in \text{Steps}(s)$ is represented by a thick arrow leading from $s$ to $t$. The starting state has an extra incoming arrow and the state labelling is written in brackets.

![Diagram](image-url)

**Fig. 6.** The roulette player.

Figure 6 shows a simplified roulette player who keeps placing bets until his wife comes to the casino. That explains the nondeterministic choice in the state $s_{\text{play}}$ (i.e. $\text{Steps}(s_{\text{play}}) = \{\mu_{s_{\text{play}}}^t, \mu'\}$, with $\mu'(s_{\text{won}}) = \mu'(s_{\text{lost}}) = \frac{1}{2}$). We have $L(s_{\text{won}}) = \text{won}$, $L(s_{\text{lost}}) = \text{lost}$ and $L(s') = \emptyset$ for the other states.

Observe that starting from state $s_{\text{init}}$, $\pi = s_{\text{init}}, s_{\text{play}}, \text{stop}, \text{play}, \ldots$ is the only path that is not fair. So if the system starts in $s_{\text{init}}$ and follows a fair scheduler, it will eventually reach the state $s_{\text{stop}}$. Considering the formula

$$\Phi = [\Diamond (\text{won} \land \neg \text{stop})]_{0.5}$$

it is easy to see that

$$s_{\text{init}} \not|=_{\text{all}} \Phi \quad \text{but} \quad s_{\text{init}} \models_{\text{fair}} \Phi.$$
3.2 Model Checking of PCTL against a PNS

Given a PNS $T = (S, \text{Steps}, AP, L, \bar{s})$, a set $\text{Sched}$ of schedulers for $T$ and a PCTL state formula $\Phi$, we want to decide, which states in $S$ satisfy the formula $\Phi$ with respect to the schedulers under consideration.\(^1\)

In this section we present a model checking algorithm for this problem which is very similar to the one for PDS (see section 2.4). As in section 2.4, we first build the parse tree of the given formula $\Phi$. We then process the parse tree bottom up, computing the satisfaction sets of the subformulae of $\Phi$ (i.e. $\text{Sat}(\Phi') = \{s \in S : s \models_S \text{Sched} \Phi'\}$, where $\Phi'$ is a subformula of $\Phi$).

As before we have $\text{Sat}(\text{true}) = S$, $\text{Sat}(a) = \{s \in S : L(s) = a\}$, $\text{Sat}(-\Phi') = S \setminus \text{Sat}(\Phi')$ and $\text{Sat}(\Phi_1 \land \Phi_2) = \text{Sat}(\Phi_1) \cap \text{Sat}(\Phi_2)$ (independent of the chosen set $\text{Sched}$ of schedulers). So the only case left is $\Phi' = [\phi]_{\text{PNS}}$, where $\phi$ is a PCTL path formula, i.e. $\phi = X\Phi'$ or $\phi = \Phi_1 U \preceq \Phi_2$ or $\phi = \Phi_1 U \Phi_2$, with $t \in \mathbb{N}$. The cases concerning the next-step and bounded-until operator will be explained in the following section and how to deal with the unbounded-until operator will be explained afterwards.

**Next-Step and Bounded-Until operator**

We first describe the procedure for $s \models_{\text{all}} [X \Phi']_{\text{PNS}}$ in detail. Following the semantics we have

$$s \models_{\text{all}} [X \Phi']_{\text{PNS}} \iff \text{prob}_s^B(\{\pi \in \text{Paths}_{\text{inf}}^B(s) : \pi^1 \in \text{Sat}(\Phi')\}) \geq p \ \forall B \in \text{Sched}_{\text{all}}.$$ 

For $B \in \text{Sched}_{\text{all}}$ we have

$$\text{prob}_s^B(\{\pi \in \text{Paths}_{\text{inf}}^B(s) : \pi^1 \in \text{Sat}(\Phi')\}) = \sum_{s' \in \text{Sat}(\Phi')} B(s^0)(s').$$

Since every possible distribution in $\text{Steps}(s)$ can be chosen by a scheduler and since we have to quantify over all schedulers, we get

$$s \models_{\text{all}} [X \Phi']_{\geq p} \iff \min_{\mu \in \text{Steps}(s)} \sum_{s' \in \text{Sat}(\Phi')} \mu(s') \geq p,$$

where the latter can easily be checked algorithmically. Observe that the case $s \models_{\text{all}} [X \Phi']_{\leq p}$ is dealt with in the same way by replacing $\min$ by $\max$.

Due to the fact that each mapping $B : \{\omega \in \text{Paths}_{\text{fin}} : |\omega| \leq t\} \rightarrow \bigcup_{s \in S} \text{Steps}(s)$ with $B(\omega) \in \text{Steps}(\text{last}(\omega))$ can be extended in a fair way, we get the same results for $s \models_{\text{Sched}} [X \Phi']_{\geq p}$ and $s \models_{\text{Sched}} [\Phi_1 U \preceq \Phi_2]_{\geq p}$ independent of what $\text{Sched}$ was chosen to be. That leaves us with

\(^1\) Remember, that we are only interested in $\text{Sched} \in \{\text{Sched}_{\text{all}}, \text{Sched}_{\text{fair}}\}$. 

Lemma 4.

\[ s \models \text{Sched } [\mathcal{X}\Phi]_{\geq p} \iff \min_{\mu \in \text{Steps}(s)} \sum_{s' \in \text{Sat}(\Phi')} \mu(s') \geq p \]

\[ s \models \text{Sched } [\mathcal{X}\Phi]_{\leq p} \iff \max_{\mu \in \text{Steps}(s)} \sum_{s' \in \text{Sat}(\Phi')} \mu(s') \leq p \]

for Sched \in \{\text{Sched}_{\text{all}}, \text{Sched}_{\text{fair}}\}.

Having taken care of the case [\mathcal{X}\Phi]_{\geq p}, we now turn our attention to the case [\Phi_1 U^S t \Phi_2]_{\geq p} for which we give a recursive computation similar to the one in section 2.4 about PDS. The difference is, that this time we have to make sure to make the “worst” choice (of scheduler) in each step. The following lemma shows precisely what this means.

Lemma 5.

Let Sched \in \{\text{Sched}_{\text{all}}, \text{Sched}_{\text{fair}}\}. For all s \in S and j \in \mathbb{N}_0 we define \(p_{s,j}^{\text{max}}\) and \(p_{s,j}^{\text{min}}\) as follows:

- if \(s \in \text{Sat}(\Phi_2)\), then \(p_{s,j}^{\text{max}} = p_{s,j}^{\text{min}} = 1 \ \forall j \in \mathbb{N}_0\)
- if \(s \not\in \text{Sat}(\Phi_1) \cup \text{Sat}(\Phi_2)\), then \(p_{s,j}^{\text{max}} = p_{s,j}^{\text{min}} = 0 \ \forall j \in \mathbb{N}_0\)
- if \(s \in \text{Sat}(\Phi_1) \setminus \text{Sat}(\Phi_2)\), then \(p_{s,0}^{\text{min}} = p_{s,0}^{\text{max}} = 0\).

\[ p_{s,j}^{\text{min}} = \min_{\mu \in \text{Steps}(s)} \sum_{t \in S} \mu(t) \cdot p_{t,(j-1)}^{\text{min}}, \]

\[ p_{s,j}^{\text{max}} = \max_{\mu \in \text{Steps}(s)} \sum_{t \in S} \mu(t) \cdot p_{t,(j-1)}^{\text{max}}. \]

Then, for all \(s \in S:\)

\[ s \models \text{Sched } [\Phi_1 U^S t \Phi_2]_{\geq p} \iff p_{s,j}^{\text{min}} \geq p \quad \text{and} \quad s \models \text{Sched } [\Phi_1 U^S t \Phi_2]_{\leq p} \iff p_{s,j}^{\text{max}} \leq p \]

Proof:

It can be shown by induction on \(j\), that

\[ p_{s,j}^{\text{extr}} = \text{extr}_{\text{Sched}} \text{prob}^B \{\pi \in \text{Paths}^B_{\text{inj}}(s) : \pi \models \text{Sched } \Phi_1 U^j \Phi_2\}, \]

where extr \in \{\text{min}, \text{max}\}, thus yielding the claim.

The Unbounded-Until Operator

In contrary to the Next-Step and Bounded-Until operators, we have to distinguish different cases for the satisfaction relation of the Unbounded-Until operator according to the chosen set of schedulers.

So we first consider the case where the chosen set of schedulers is Sched_{all}. Given a state \(s\) we want to decide whether \(s\) satisfies \([\Phi_1 U \Phi_2]_{\geq p}\), which is equivalent to

\[ p^B_s (\Phi_1 U \Phi_2) := \text{prob}^B_s (\{\pi \in \text{Paths}^B_{\text{inj}}(s) : \pi \models_{\text{all}} \Phi_1 U \Phi_2\}) \geq p \ \forall B \in \text{Sched}_{\text{all}}. \]
By the results of [10] we know that

\[ \sup \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{all} \} = \max \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{simple} \} \quad \text{and} \]

\[ \inf \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{all} \} = \min \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{simple} \}. \]

From now on we denote \( \max \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{simple} \} \) by \( p_s^{max}(\Phi_1 \cup \Phi_2) \) and \( \min \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{simple} \} \) by \( p_s^{min}(\Phi_1 \cup \Phi_2) \).

Since \( Sched_{simple} \subseteq Sched_{all} \), we know that the supremum and infimum are really maximum and minimum. This fact gives rise to the following lemma.

**Lemma 6.**

\[ s \models_{all} [\Phi_1 \cup \Phi_2] \leq p \iff p_s^{max}(\Phi_1 \cup \Phi_2) \leq p \iff s \models_{simple} [\Phi_1 \cup \Phi_2] \leq p \]

We will describe later (see section 3.2) how to compute the values \( p_s^{max}(\Phi_1 \cup \Phi_2) \) and \( p_s^{min}(\Phi_1 \cup \Phi_2) \).

Now we consider the case where the chosen set of schedulers is \( Sched_{fair} \). Given a state \( s \), we want to decide, whether

\[ \prob^B_s \left( \{ \pi \in Paths^B_{in,f}(s) : \pi \models_{fair} \Phi_1 \cup \Phi_2 \} \right) \gg p \quad \forall B \in Sched_{fair}. \]

Here we have to deal with \( \gg \in \{ \geq, > \} \) and \( \gg \in \{ \leq, < \} \) in two different ways.

1. \( \gg \in \{ \leq, < \} \): Since \( p_s^{max}(\Phi_1 \cup \Phi_2) = \max \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{all} \} \) (see above), it obviously holds that

\[ p_s^{max}(\Phi_1 \cup \Phi_2) \geq p_F(\Phi_1 \cup \Phi_2) \quad \forall F \in Sched_{fair}. \]  

(1)

Let now \( B \) be a scheduler such that \( p_s^B(\Phi_1 \cup \Phi_2) = p_s^{max}(\Phi_1 \cup \Phi_2) \). It can be shown (see [4]) that there is a fair scheduler \( F_B \) with

\[ p_s^{F_B}(\Phi_1 \cup \Phi_2) \geq p_s^B(\Phi_1 \cup \Phi_2) = p_s^{max}(\Phi_1 \cup \Phi_2). \]

(2)

From (1) and (2) it follows, that

\[ \sup \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{fair} \} = \max \{ p_s^B(\Phi_1 \cup \Phi_2) : B \in Sched_{fair} \} = p_s^{max}(\Phi_1 \cup \Phi_2), \]

which yields

**Lemma 7.**

\[ s \models_{fair} [\Phi_1 \cup \Phi_2] \leq p \iff p_s^{max}(\Phi_1 \cup \Phi_2) \leq p. \]

---

12. Note, that the set \( Sched_{simple} \) is finite.

13. This does not hold for \( PCTL^* \) formulae. For a counterexample see section 4.
$\infty \in \{\geq, >\}$: This case differs a little from the others. First, we give an example that shows that this case cannot be handled like the other cases. Consider the following PNS $T = \{s, t\}, \text{Steps}, \{a, b\}, L, s$ with \text{Steps}(s) = $\{\mu_s, \mu_t\}$, \text{Steps}(t) = $\{\mu_t\}$, $L(s) = \{a\}$ and $L(t) = \{b\}$.

For the simple scheduler $B$ with $B(s) = \mu_s^1$ (and $B(t) = \mu_t^1$) we get $p^B_s(alb) = 0$, thus $p^\min_s(alb) = 0$. On the other hand we have $p^F_s(alb) = 1$ for each fair scheduler $F$ and therefore $s \models_{\text{fair}} (alb)$. The problem in this example is, that the simple scheduler $B$ with $B(s) = \mu_s^1$ forces the process to stay forever in the “non-successful” state $s$ from which the “successful” state $t$ can be reached. In contrary to this it can be shown for fair schedulers, that with probability 1 all states that are reachable from a state that is visited infinitely often, are also visited infinitely often. This explains, why $p^\min_s(alb)$ cannot be “approximated” by fair schedulers. We now introduce some notation we will need to explain how to decide whether $s \models_{\text{fair}} [\Phi_1 U \Phi_2]_{\geq 1}$.

**Definition 24. [The sets $U_{>0}$ and $U_?$ and the corresponding atomic propositions]**

Let $U_{>0}$ be the set of states for which there is a scheduler $B$, such that $p^B_s(\Phi_1 U \Phi_2) > 0$, i.e.

$$U_{>0} = \{s \in S : p^\max_s(\Phi_1 U \Phi_2) > 0\}.$$ 

Let $U_? = U_{>0} \setminus \text{Sat}(\Phi_2)$.

Extend the set $\text{AP}$ by two new atomic propositions $a_{>0}$ and $a_?$ and the labelling by $a_{>0} \in L(s) \iff s \in U_{>0}$ and $a_? \in L(s) \iff s \in U_?$. So $s \in U_{>0}$ if and only if starting from $s$ it is possible to satisfy the formula $\Phi_1 U \Phi_2$.

For each fair scheduler $F$ and each state $s$, it can be shown (see [4]), that $\text{prob}_F^F(\{\pi \in \text{Paths}_{\inf}^F(s) : \pi \models_{\text{fair}} \Phi_1 U \Phi_2 \text{ or } \pi \models_{\text{fair}} \text{true} U \neg a_{>0}\}) = 1$.

That means, if the process follows the fair scheduler $F$, then with probability 1 the process will either satisfy the formula $\Phi_1 U \Phi_2$ or will eventually reach a state that is not contained in $U_{>0}$. In other words, the set of infinite paths complying with the scheduler $F$ and staying in $U_?$ forever, is a nullset (with respect to the measure defined by $F$). Since the set $\{\pi \in \text{Paths}_{\inf}^F(s) : \pi \models_{\text{fair}} \Phi_1 U \Phi_2 \text{ or } \pi \models_{\text{fair}} \text{true} U \neg a_{>0}\}$ is the disjoint union of the two
sets \( \{ \pi \in \text{Paths}^F_{\text{inf}}(s) : \pi \models \text{fair } \Phi_1 \cup \Phi_2 \} \) and \( \{ \pi \in \text{Paths}^F_{\text{inf}}(s) : \pi \models \text{fair } a; \mathcal{U} \neg a > 0 \} \), it follows from the above, that
\[
\begin{align*}
\text{prob}^F_s(\{ \pi \in \text{Paths}^F_{\text{inf}}(s) : \pi \models \text{fair } \Phi_1 \cup \Phi_2 \}) &= \\
1 - \text{prob}^F_s(\{ \pi \in \text{Paths}^F_{\text{inf}}(s) : \pi \models \text{fair } a; \mathcal{U} \neg a > 0 \}).
\end{align*}
\]

So we get
\[
s \models \text{fair } [\Phi_1 \cup \Phi_2] \geq p \iff p^F_s(\Phi_1 \cup \Phi_2) \geq p \quad \forall F \in \text{Sched}_{\text{fair}} \iff \\
p^F_s(a; \mathcal{U} \neg a > 0) \leq 1 - p \quad \forall F \in \text{Sched}_{\text{fair}} \iff p^\text{max}_s(a; \mathcal{U} \neg a > 0) \leq 1 - p,
\]
which leads to the following lemma

**Lemma 8.**
\[
s \models \text{fair } [\Phi_1 \cup \Phi_2] \geq p \iff p^\text{max}_s(a; \mathcal{U} \neg a > 0) \leq 1 - p.
\]

The only open question is how to efficiently compute the set \( U_{>0} \), \( U_1 \) and the values \( p^\text{max}_s(\Phi_1 \cup \Phi_2) \) and \( p^\text{min}_s(\Phi_1 \cup \Phi_2) \), if the sets Sat(\( \Phi_1 \)) and Sat(\( \Phi_2 \)) have already be computed.

**The Computation of** \( p^\text{max}_s(\Phi_1 \cup \Phi_2), p^\text{min}_s(\Phi_1 \cup \Phi_2) \) **and the set** \( U_{>0} \)

Recall, that
\[
U_{>0} = \{ s \in S : p^\text{max}_s(\Phi_1 \cup \Phi_2) > 0 \}.
\]

So we could compute \( U_{>0} \), by computing the values \( p^\text{max}_s(\Phi_1 \cup \Phi_2) \) for all \( s \in S \). But it is also easy to see, that \( s \in U_{>0} \) if and only if starting from \( s \), one can reach a state in Sat(\( \Phi_2 \)) via a path in Sat(\( \Phi_1 \)), i.e. \( \exists \omega \in \text{Paths}_{\text{fin}}(s) \) such that \( \text{last}(\omega) \in \text{Sat}(\Phi_2) \land \omega^i \in \text{Sat}(\Phi_1), \ i = 0, 1, \ldots, \text{last}(\omega) - 1 \).

So a more efficient way for computing \( U_{>0} \) is to perform a backwards reachability analysis from the states in Sat(\( \Phi_2 \)) within the states of Sat(\( \Phi_1 \)). Making this idea precise, we define the directed graph \( G_{>0}(\Phi_1 \cup \Phi_2) = (S, E_{>0}) \), where
\[
E_{>0} = \{(s, t) \in S \times S \mid t \in \text{Sat}(\Phi_1) \setminus \text{Sat}(\Phi_2) \land \exists \mu \in \text{Steps}(t) : \mu(s) > 0\}.
\]

Then
\[
U_{>0} = \{ s \in S \mid s \text{ can be reached in } G_{>0}(\Phi_1 \cup \Phi_2) \text{ from a state } s \in \text{Sat}(\Phi_2) \},
\]
so \( U_{>0} \) can be computed by a depth first search in \( G_{>0}(\Phi_1 \cup \Phi_2) \).

To compute \( p^\text{max}_s(\Phi_1 \cup \Phi_2), s \in S \), one can use linear programming techniques. It can be shown (see [10, 14]), that the values \( p^\text{max}_s(\Phi_1 \cup \Phi_2), s \in S \) are the unique solution of the linear minimization problem
\[
\begin{align*}
x_s = 1 & \quad \text{if } s \in \text{Sat}(\Phi_2) \\
x_s = 0 & \quad \text{if } s \notin U_{>0} \\
x_s \geq \sum_{t \in S} \mu(t) \cdot x_t & \quad \text{if } s \in \text{Sat}(\Phi_1) \setminus \text{Sat}(\Phi_2), \ \mu \in \text{Steps}(s),
\end{align*}
\]
where $\sum_{s \in S} x_s$ is minimized.

This problem can be solved by well known methods like the ellipsoid method or the simplex method. For $p^*_{s\min}(\Phi_1 \cup \Phi_2)$ one gets an analogous linear maximization problem.

For reasons of completeness we also want to mention that one can use the characterization of the function $s \mapsto p^*_{s\max}(\Phi_1 \cup \Phi_2)$ as the least fixed points of certain operators on certain function spaces and compute (resp. approximate) those values with iterative methods (see [5]).

The algorithm

Now we have everything on hand to present a model checking algorithm for PCTL formulae against a PNS. As mentioned, one can build the parse tree of the given formula (or the parse graph to avoid multiple computations) and compute the satisfaction sets for the subformulae in a bottom up manner. In algorithm 3 and 4 we present a method that calculates the satisfaction sets recursively, so in an actual implementation one had to ensure that there were no multiple calls for syntactically identical subformulae.

**Algorithm 3 PCTL\_MODELCHECK**

**Input:** $PNS T = (S, Steps, AP, L, \bar{s})$, PCTL state formula $\Phi$ over AP, string $\in \{all, fair\}$

**Output:** truth value of $\bar{s} \models_{\text{string}} \Phi$

\[
\text{IF } \bar{s} \in \text{Sat}(\Phi, \text{string}) \text{ THEN }
\text{return true}
\]

\[
\text{ELSE}
\text{return false}
\]

The Complexity of PCTL model checking against a PNS

In this paragraph we briefly estimate the time and space complexity of our model checking algorithm. Given a $PNS T$ and a PCTL state formula $\Phi$ we denote by $n$ the number of states of $T$, i.e. $n = |S|$ and by $m$ the number of transitions of $T$, i.e. $m = \sum_{s \in S} |Steps(s)|$. The number of subformulae of $\Phi$ is linear in $|\Phi|$.

- For a subformula $\Phi'$, where $\Phi'$ is true, an atomic proposition $a$ or of the form $\neg \Phi''$ or $\Phi_1 \land \Phi_2$, the set $\text{Sat}(\Phi')$ can be computed in time $O(n)$.
- If the subformula $\Phi'$ is of the form $[a \Phi'']_{\text{ap}}$, the set $\text{Sat}(\Phi')$ can be computed in time $O(m \cdot n)$, since for every $s \in S$ we have to compute the sum $\sum_{t \in \text{Sat}(\Phi'')} \mu(t)$ for every $\mu \in \text{Steps}(s)$.
- If the subformula $\Phi'$ is of the form $[\Phi_1 \cup \Phi_2]_{\text{ap}}$, the set $\text{Sat}(\Phi')$ can be computed in time $O(t \cdot m \cdot n)$ (see algorithm).
Algorithm! 4 Sat(\(\Phi\), string)

Input:

Output: Set of all \(s \in S\) that satisfy \(\Phi\) with respect to the chosen set of schedulers

**CASE** \(\Phi\) is

true : return \(S\)

\(a\) : return \(\{s \in S : a \in L(s)\}\)

\(\Phi_1 \land \Phi_2\) : return \(Sat(\Phi_1, string) \cap Sat(\Phi_2, string)\)

\(\neg \Phi'\) : return \(S \setminus Sat(\Phi', string)\)

\([\chi \Phi']_\geq p\) : compute \(Sat(\Phi', string)\);

\(\forall s \in S : p^\min_X(s) = \min_{\mu \in \text{Steps}(s)} \sum_{t \in S} \mu(t)\); return \(\{s \in S : p^\min_X(s) \geq p\}\)

\([\chi \Phi']_\leq p\) : compute \(Sat(\Phi', string)\);

compute \(p^\max_X(s) = \max_{\mu \in \text{Steps}(s)} \sum_{t \in S} \mu(t)\); return \(\{s \in S : p^\max_X(s) \leq p\}\)

\([\Phi_1 \cup \leq \Phi_2]_\geq p\) : compute \(Sat(\Phi_1, string)\) and \(Sat(\Phi_2, string)\);

\(\forall s \in S : p^\min_{\Phi_0}(s) = \begin{cases} 1 & \text{if } s \in Sat(\Phi_2, string) \\ 0 & \text{otherwise} \end{cases}\)

FOR \(i = 1\) to \(t\) DO

\(\forall s \in S : p^\min_{\Phi_0}(s) = \begin{cases} 0, & \text{if } s \notin Sat(\Phi_1, string) \cup Sat(\Phi_2, string), \\ 1, & \text{if } s \in Sat(\Phi_2, string), \\ \min_{\mu \in \text{Steps}(s)} \sum_{t \in S} \mu(t) \cdot p^\min_{\Phi_0}(t) & \text{otherwise} \end{cases}\)

OD return \(\{s \in S : p^\min_{\Phi_0}(s) \geq p\}\)

\([\Phi_1 \cup \leq \Phi_2]_\leq p\) : as above, replace “\(\geq\)” by “\(\leq\)” and “\(\min\)” by “\(\max\)”

\([\Phi_1 \cup \Phi_2]_\leq p\) : compute \(Sat(\Phi_1, string)\) and \(Sat(\Phi_2, string)\);

compute \(p^\max_{\Phi_1 \cup \Phi_2}\) by solving a linear minimization problem; return \(\{s \in S : p^\max_{\Phi_1 \cup \Phi_2} \leq p\}\)

\([\Phi_1 \cup \Phi_2]_\geq p\) : compute \(Sat(\Phi_1, string)\) and \(Sat(\Phi_2, string)\);

IF \(string = \text{"all"}\) THEN

compute \(p^\min_{\Phi_1 \cup \Phi_2}\); return \(\{s \in S : p^\min_{\Phi_1 \cup \Phi_2} \leq p\}\)

ELSE (*string = "Tan"*)

compute \(U_{>0}, U_{=}\) and the labeling for \(a_{>0}, a_{=}\);

compute \(p^\max_{(a \cup \neg a_{>0})}\); return \(\{s \in S : p^\max_{(a \cup \neg a_{>0})} \leq 1 - p\}\)

ENDIF

END CASE
If the subformula $\Phi'$ is of the form $[\Phi_1 \cup \Phi_2]_{\leq p}$, the set $Sat(\Phi')$ can be computed in time $O(poly(m, n))$. As mentioned above, $p^{max}_s(\Phi_1 \cup \Phi_2)$, resp. $p^{\min}_s(\Phi_1 \cup \Phi_2)$ can be computed with well known methods (e.g. Ellipsoid-, Karmarkar-method), which need polynomial time in the size of the problem. The needed graph analyses have time complexity $O(m \cdot n)$.

Summing up over all subformulae of $\Phi$, we get, that the model checking algorithms needs time

$$O(|\Phi| \cdot (t_\Phi \cdot m \cdot n + p(m, n))),$$

where $t_\Phi$ stands for the maximal $t$ in subformulae of the form $\Phi_1 \cup \Phi_2$\footnote{If there is no such subformula in $\Phi$, then $t_\Phi$ is 1.} and $p(n, m)$ is a polynomial that represents the costs for solving the linear optimization problems.

For the estimation of the space complexity we assume w.l.o.g. that $n \leq m$. To represent the system $T$ itself, we need space $O(m \cdot n)$ (neglecting the representation for the labelling function $L$). For each subformula $\Phi'$, the set $Sat(\Phi')$ requires space $O(n)$. The needed graph analyses require space $O(m \cdot n)$ and for the computation of $p^{\max}_s(\Phi_1 \cup \Phi_2)$, resp. $p^{\min}_s(\Phi_1 \cup \Phi_2)$ space $O(n^2)$ is needed. Altogether this leads us to the following theorem:

**Theorem 2.**

Let $T$ be a PNS and $\Phi$ a PCTL state formula over the set of atomic propositions of $T$. Then $Sat(\Phi)$ can be computed in time and space linear in the size of $\Phi$ and polynomial in the size of $T$ if the set of schedulers under consideration is $Sched_{all}$ or $Sched_{fair}$.

**Remark 7.**

In [4] another classification of schedulers is considered, namely strict fair schedulers. We call a scheduler $B$ strictly fair if and only if all infinite paths that comply with $B$ are fair. By $Sched_{sfair}$ we denote the set of strictly fair schedulers. For $\models_{Sched_{sfair}}$ some of the above calculations (the Unbounded-Until cases) are a little bit more complicated than for the fair schedulers (for details see [4]). However the results of theorem 2 still hold, if the set of schedulers under consideration is $Sched_{sfair}$.

### 3.3 Model Checking of PCTL$^*$ against a PNS

As in the deterministic case (see section 2.5) the model checking of PNS is extended to PCTL$^*$-formulae as well. In this section we explain how to model check a PNS against a PCTL$^*$-formula. Throughout this section let $T = (S, STEPS, AP, L, s)$ be a PNS. It follows from remark 4 that it is sufficient to consider formulae which do not make use of $[\cdot]_{> p}$ and $[\cdot]_{\geq p}$. The basic procedure is similar to the one in section 2.5. Let $\Phi$ be a PCTL$^*$ state formula. We only consider $\Phi$ to be of the form $\Phi = [\varphi]_{\leq p}$ since the other cases are either trivial or
can be reduced to this one (see above). As in the deterministic case, we assume, that we have already computed (recursively) the satisfaction sets of all maximal state subformulæ \( \gamma_1, \ldots, \gamma_n \) of \( \phi \), so we can view them as atomic propositions. Then \( \phi \) is a LTL formula over \( \{ \gamma_1, \ldots, \gamma_n \} \). [10] presents a model checking algorithm for \( pCTL^* \) (which essentially coincides with our \( PCTL^* \)) that uses a normal form for the LTL formula \( \phi \). In [18, 17], an alternative method is considered, which uses the representation of LTL formulæ by \( \omega \)-automata and runs in time polynomial in the size of the system and doubly-exponential in the size of the formula (thus, this method meets the lower bound presented in [15]). In [10] and [18, 17] only the relation \( \models_{\text{all}} \) is considered. We will first present briefly the model checking algorithm of [18, 17] and then explain, how it can be modified to handle fairness (see [4]).

The first step is the same for both cases (\( \models_{\text{all}} \) and \( \models_{\text{fair}} \). As in section 2.6, we construct a deterministic Rabin automaton \( A = (\Sigma, Q, q_0, \rho, \alpha) \) such that \( L_{\omega}(A) = L_{\omega}(\phi) \). Recall that the size of the automaton \( A \) is doubly exponential in \( |\phi| \) and that a run \( r \) of \( A \) is accepting if and only if there exists \( (L, U) \in \alpha \), such that \( \text{lim}(r) \cap L \neq \emptyset \) and \( \text{lim}(r) \cap U = \emptyset \). After constructing the automaton \( \mathcal{A} \), we build the product \( PNS T' = T \times A = (S \times Q, \text{Steps}', \text{AP}, L', (s, q)) \), where

- \( \mu' \in \text{Steps}'((s, q)) \iff \exists \mu \in \text{Steps}(s), \text{ s.t. } \mu'((t, p)) = \mu(t), \text{ if } p = \rho(q, L(s)) \) and 0 otherwise.
- \( L'((s, q)) = L(s) \).

Let \( \alpha' \) be the lifted acceptance condition from \( \mathcal{A} \), i.e.

\[
\alpha' = \{ (S \times L, S \times U) \mid (L, U) \in \alpha \}.
\]

As in the deterministic case we get a one-to-one correspondence between the infinite paths of \( T \) and \( T' \) by path lifting which works as follows:

- First we embed \( S \) into \( S \times Q \) by \( s \mapsto (s, q_s) \), where \( q_s = \rho(q, L(s)) \).
- Let \( \pi = s_0 \xrightarrow{\mu_1} s_1 \xrightarrow{\mu_2} s_2 \ldots \) be an infinite path of \( T \). The induced infinite paths \( \pi' \) of \( T' \) is given by

\[
\pi' = (s_0, p_0) \xrightarrow{\mu'_1} (s_1, p_1) \xrightarrow{\mu'_2} (s_2, p_2) \ldots,
\]

where \( p_0 = q_s, p_{i+1} = \rho(p_i, L(s_i)) \) and

\[
\mu'_1((t, p)) = \begin{cases} 
\mu_i(t) & \text{if } p = \rho(p_{i-1}, L(s_{i-1})) \\
0 & \text{otherwise.}
\end{cases}
\]

The case \( \models_{\text{all}} \)

This case is very similar to the deterministic case, where accepting ergodic sets played an important role. Since now we have to quantify over all schedulers, we give the definition of a \textit{maximal end component}, which is the pendant to an ergodic set in a Markov chain.
Definition 25. [sub-PNS]
Given a PNS $T = (S, \text{Steps}, AP, L, \bar{s})$, a sub-PNS of $T$ is a tuple $T' = (S', \text{Steps}')$ such that
- $S' \subseteq S$ and
- $\text{Steps}'(s') \subseteq \text{Steps}(s') \ \forall s' \in S'$.

Note, that a sub-PNS $T'$ of a PNS $T$ (even when equipped with a state labelling and a starting state) is not a PNS, because $\text{Steps}'$ maps a state $s'$ from $T'$ to a probability distribution on the states of $T$, so it can happen that $\text{supp}(\mu) \supset S'$ for some $\mu \in \text{Steps}'(s')$ for some $s' \in S'$.

Definition 26. [End Component]
We call a sub-PNS $T' = (S', \text{Steps}')$ an end component if:
- $\forall s' \in S': \text{supp}(\mu) \subseteq S' \ \forall \mu \in \text{Steps}'(s')$.
- The graph $(S', E_{T'})$ is strongly connected,
  where $E_{T'} = \{(s', t'): s', t' \in S' \text{ and } \exists \mu \in \text{Steps}'(s') : \mu(t') > 0\}$.

Note that because of the first requirement, an end component is (accept for the lacking state labelling and the missing starting state) a PNS. The second requirement ensures, that for each pair $(s', t')$ of states, there is always a scheduler, such that there is a finite path from $s'$ to $t'$. It also holds, that given any starting state and a scheduler of a PNS, the induced process will end up with probability 1 in an end component (thus the name “end component”)(see [18]).

We say that an end component $(S', \text{Steps}')$ is contained in another end component $(S'', \text{Steps}'')$ if
- $S' \subseteq S''$ and
- $\text{Steps}'(s') \subseteq \text{Steps}''(s') \ \forall s' \in S'$.

Definition 27. [Maximal End Component]
An end component of a PNS $T$ is called maximal if it is not contained in any other end component of $T$.

As said before, maximal end components are the pendant to ergodic sets in Markov chains. So the rest of the procedure is very similar to the deterministic case.

We call a maximal end component $(S', \text{Steps}')$ of $T'$ accepting, if $S'$ satisfies the acceptance condition $\alpha'$. Let

$$\text{Acc}' = \{S' \mid (S', \text{Steps}') \text{ is an accepting maximal end component of } T'\}.$$ 

Let $\text{acc}$ be a new atomic proposition such that $\text{acc} \in L'(s')$ if and only if $s' \in \text{Acc}'$. One can then show (see [18]), that

$$\sup_{B \in \text{Sched}_{all}} \text{prob}_{s}^{B}(|\pi | \pi \in \text{Paths}_{inf}^{B}(s) : \pi \models_{\text{all}} \phi|) =$$

$$\sup_{B' \in \text{Sched}_{all}} \text{prob}_{(s, q_{s})}^{B'}(|\pi' | \pi' \in \text{Paths}_{inf}^{B'}((s, q_{s}) : \pi' \models_{\text{all}} \text{\text{\textbackslash}}\text{acc}|),$$

where the latter quantity can be computed by the means of section 3.2. This leads to the following lemma.
Lemma 9.

\[ s \models_{\text{alt}} [\phi] \leq_p \iff (s, q_s) \models_{\text{alt}} [\Diamond \text{acc}] \leq_p. \]

So we get

\[ \text{Sat}(\Phi) = \{ s \in S \mid p^\text{max}_{(s, q_s)}(\Diamond \text{acc}) \leq_p \}. \]

The case \( \models_{\text{fair}} \)

Not only do we have a one-to-one correspondence between the infinite paths of \( T \) and \( T' \) but it holds also, that the infinite path \( \pi \) of \( T \) is fair if and only if the corresponding path \( \pi' \) of \( T' \) is fair. We even get that each fair scheduler \( B \) of \( T \) induces a fair scheduler \( B' \) of \( T' \), such that \( \text{Paths}^B_{\text{inf}} = \{ \pi' \mid \pi \in \text{Paths}^B_{\text{inf}} \} \). In addition, the associated probability spaces on \( \text{Paths}^B_{\text{inf}}(s) \) and \( \text{Paths}^{B'}_{\text{inf}}(s, q_s) \) are isomorphic.

For each \( (L', U') \in \alpha' \), let \( \text{Acc}'(L', U') \) be the union of all subsets \( T' \) of \( S \times Q \) such that \( T' \cap U' = \emptyset \) and for all \( t' \in T' \) the following hold:

- \( \text{supp}(\mu') \subseteq T' \) for all \( \mu' \in \text{Steps}(t') \)
- \( \text{reach}(t') \cap L' \neq \emptyset \).

Let \( \text{Acc}' = \bigcup_{(L', U') \in \alpha'} \text{Acc}'(L', U') \) and let \( \text{acc} \) be an atomic proposition such that \( \text{acc} \in L'(s') \) if and only if \( s' \in \text{Acc}' \).

It then follows (see [4]) for all fair schedulers \( F' \) of \( T' \), that

\[ \text{prob}^F_{\text{acc}} = \text{prob}^{F'}_{\text{acc}}(\{ \pi' \in \text{Paths}^F_{\text{inf}}(s') : L'(\pi^0), L'(\pi^1), \ldots \in \mathbb{L}_\omega(A) \}). \]

Therefore we get the following lemma.

Lemma 10.

\[ s \models_{\text{fair}} [\phi] \leq_p \iff (s, q_s) \models_{\text{fair}} [\Diamond \text{acc}] \leq_p. \]

So in order to compute the set \( \text{Sat}(\Phi) = \text{Sat}([\phi] \leq_p) \), we have to compute the values \( p^\text{max}_{(s, q_s)}(\Diamond \text{acc}) \) for \( T' \) by the means of section 3.2, i.e.

\[ \text{Sat}(\Phi) = \{ s \in S \mid p^\text{max}_{(s, q_s)}(\Diamond \text{acc}) \leq_p \}. \]

4 Concluding Remarks

In this paper we gave an overview of the logics \( PCTL \) and \( PCTL^* \) and model checking algorithms for deterministic and nondeterministic (finite-state) probabilistic systems. Here, we followed the state-labelled approach. Action-labelled variants of \( PCTL/PCTL^* \) have been investigated as well, see e.g. [47, 45, 23, 9].

---

\[15\] Where \( \text{reach}(t') \) denotes the set of states that are reachable from \( t' \), i.e. \( \text{reach}(t') = \{ s \in S \mid \exists \omega \in \text{Paths}_{\text{fin}} : t' = \text{first}(\omega) \text{ and } s = \text{last}(\omega) \} \).
In the remainder of this section we want to give a short overview on furthergoing topics.

In section 3.1 we defined schedulers for a $PNS$. There is a more general definition of schedulers, the so called stochastic schedulers. Given a probabilistic nondeterministic system $T$, a stochastic scheduler of $T$ is a function $B$ mapping every finite path $\omega$ of $T$ to a distribution $B(\omega) \in Distr(Steps(last(\omega)))$.

That means, after the process described by the $PNS$ performed the first $|\omega|$ steps, the scheduler $B$ chooses with the probability $B(\omega)(\mu)$ the next transition to be $\mu$, for $\mu \in Steps(last(\omega))$. So if a system behaves according to a scheduler $B$ and has followed the sequence $\omega = s_0, s_1, \ldots, s_n$ so far, then it will be in state $t$ in the next step with probability

$$\sum_{\mu \in Steps(s_n)} B(\omega)(\mu) \cdot \mu(t).$$

Giving a stochastic scheduler $B$ we can define a probability space in the straightforward way. Furthermore, we can classify the stochastic schedulers into different classes (see [43]). A scheduler $B$ is said to be of the kind

- (HS), if it is history-dependent and stochastic.
- (MS), if it is stochastic and markovian, that means $B(\omega) = B(last(\omega))$ for all finite path $\omega$, i.e. $B$ is history independent.
- (HD), if it is history-dependent and deterministic, that means for all finite path $\omega : B(\omega)(\mu) \in \{0, 1\} \forall \mu \in Steps(last(\omega))$, i.e. $B$ schedules a unique next transition$^{10}$.
- (MD), if it is markovian and deterministic (also called simple).

Given a $PNS$, we will denote the set of all its stochastic schedulers by $Sched_{stoch}$. From now on we denote the set of schedulers of the kind (HD) by $Sched_{det}$, i.e. with the notations of section 3 $Sched_{det} = Sched_{all}$.

Given a $PNS$ and a $PCTL$ path formula $\phi$, we have already seen in section 3.2, that

$$s \models_{Sched_{det}} [\phi]_{s\mathbf{\rightarrow}} \iff s \models_{Sched_{simple}} [\phi]_{s\mathbf{\rightarrow}}.$$ 

Moreover the following holds (see [10, 27, 46]):

- Given a $PNS$ and a $PCTL$ path formula $\phi$, then for all state $s$

  $$s \models_{Sched_{stoch}} [\phi]_{s\mathbf{\rightarrow}} \iff s \models_{Sched_{simple}} [\phi]_{s\mathbf{\rightarrow}}.$$ 

- Given a $PNS$ and a $PCTL^*$ path formula $\phi$, then for all state $s$

  $$s \models_{Sched_{stoch}} [\phi]_{s\mathbf{\rightarrow}} \iff s \models_{Sched_{det}} [\phi]_{s\mathbf{\rightarrow}}.$$ 

$^{10}$ This coincides with definition 19.
An informal explanation for these results is the following: It can be shown (see [27, 46]), that the measure of a measurable set $\Omega$ w.r.t. a stochastic scheduler is a convex combination of measures of $\Omega$ w.r.t. deterministic schedulers. Since we are only interested in maximal and minimal measures, we get the above results. Hence, all methods presented in section 3 apply to stochastic schedulers as well.

Note, that for a $PCTL^*$ formula $\phi$, it is not sufficient to consider only the simple schedulers as the following example demonstrates:

Consider the $PCTL^*$ formula $\phi = \Box a \lor \Box (a \rightarrow \chi b)$. 

Observe that due to the absence of probabilistic choice, starting in s, each scheduler will schedule a unique path. There are only two simple schedulers, the one that schedules the path $\pi = s, u, s, u, s, u, \ldots$ and the one that schedules the path $\pi' = s, t, s, t, s, t, \ldots$. Both paths satisfy the formula $\phi$, so we get $s \models_{\text{Sched\_simple}} \phi \geq 1$. On the other hand, there is a scheduler in $\text{Sched\_det}$, that schedules the path $\pi'' = s, t, s, u, s, t, s, u, \ldots$. This path does not satisfy the given formula $\phi$ and we get $s \not\models_{\text{Sched\_det}} \phi \leq 0$ and therefore $s \not\models_{\text{Sched\_stoch}} \phi \leq 0$.

As in the non probabilistic setting various simulation and bisimulation relations have been defined and studied in connection with probabilistic systems [32, 30, 46, 31]. It is possible to give logical characterizations for some of these relations, e.g. for $\text{DTMC}$ bisimulation equivalence is the same as $PCTL^*$-equivalence (see e.g. [3]). Similar results for certain types of nondeterministic probabilistic systems and $PCTL^*$ have been established in [47, 29].

The state space explosion problem arises in the probabilistic setting to the same extent as in the non-probabilistic setting. In the last 10 years several methods have been developed to attack the state space explosion problem for non-probabilistic systems. Some of these approaches have been extended to the probabilistic case. In [16] a technique was introduced that involves an iterative usage of a simulation relation by starting with a small abstract model and successively refining it, until the properties under consideration are safely checked. Another approach are symbolic methods that use $MTBDDs$ (or other Decision Diagram variants) as an underlying data structure. Some of the model checking algorithms presented in this article were implemented (with several modifications) in the tool $PRISM$ ([37]) which uses standard methods of symbolic model checking (see e.g. [39, 7] and the article by D. Parker and A. Miner in this volume) and
in the tool ProbVerus [49].

A probabilistic variant of timed automata ([11]) and continuous real time extensions of PCTL were introduced and studied in [34–36]. See the article by Jeremy Sproston in this volume.

CSL, an extension of PCTL for reasoning about performance measures and quantitative temporal properties of Continuous Time Markov Chains was introduced and studied in [3, 6]. The results were implemented in e.g. $E \vdash MC^2$ [28] and PRISM [37].
